Figure 15 Measured (solid lines) and calculated (dashed lines) oblique incidence (45°) reflectivity spectra at 77 K of three short-period $(GaAs)_n/(AlAs)_n$ superlattices on GaAs substrates: n denotes the number of monolayers. Left curves: s-polarization, right curves: p-polarization. Note that the strong reststrahl reflectivity is from the GaAs substrates and the fine structure is due to confined modes. The subscripts 1, 2, and 3 denote the orders of the confined modes. Reproduced with permission from Dumelow T, Hamilton AA, Parker TJ, Tilley DR, Foxon CT, Hilton D and Moore KJ (1990) Far infrared measurements of bulk and surface phonons in GaAs/AlAs superlattices. *International Journal of Infrared and Millimeter Waves* 11: 901.

quality of the interfaces in such structures is important as it determines the amount of electronic scattering at the interfaces. Some structures are fabricated from alternate layers of materials such as GaAs and AlAs, in which there is no overlap between the frequencies of the optical branches of the phonon dispersion curves. This has the effect that optical phonons excited in one type of layer, e.g., in GaAs, cannot propagate into the other type of layer, i.e., AlAs, and vice versa, so that the optical phonon modes are confined in their respective layers. The confined modes behave like standing waves, with frequencies determined by the thicknesses of the layers and the bulk optical phonon dispersion curves. Thus, if the superlattice structure is of poor quality, and the interfaces are broad due to alloying, rather than abrupt, there will be a change in the effective widths of the layers. This leads to small shifts in the frequencies of the confined phonons which can be measured and used to obtain a quantitative estimate of the amount of interface broadening. An example is shown in Figure 15. The degree of interface broadening determined from these spectra was 1.4 atomic spacings, in agreement with estimates using other techniques.

Surface phonon polaritons and guided waves

The reststrahl reflection band (Figure 6) occurs because there is a gap between ω_T and ω_L in the polariton dispersion curves (Figures 4 and 5), with no solutions for bulk phonon modes. Surface phonon polaritons can, however, propagate in this frequency band, but they have wavevectors that are larger than those, ω/c, of far-infrared radiation, so special techniques are required to observe them. The necessary wavevector enhancement can be obtained in two ways. Prism coupling can be used, as shown in Figure 16. When the angle of incidence of the incident beam at the base of the prism exceeds the critical angle for total internal reflection an evanescent wave with advanced wave vector, $q > \omega/c$, is set up at the base of the prism. This wave can couple to a surface polariton, and the energy used to excite the polariton results in a dip in the reflectivity at the frequency of the surface polariton, hence the name of the technique: attenuated total reflection (ATR). An example is shown in Figure 16. Alternatively, wavevector enhancement can be achieved by placing a grating on the surface of the sample. The incident photon wavevector is then enhanced by $+2m\pi/d$, where d is the grating period and m is an integer.

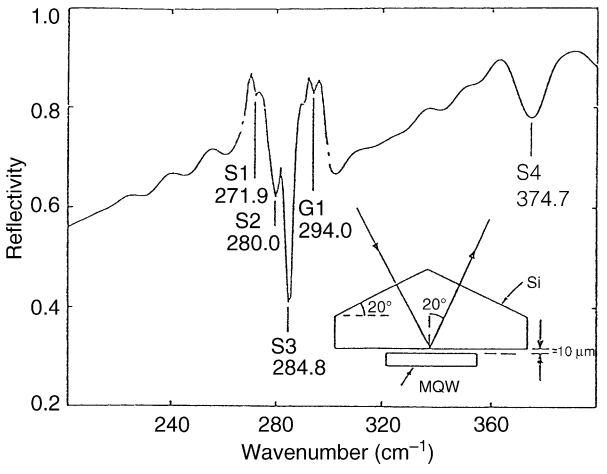

Figure 16 ATR reflection spectrum with dips due to surface phonon polaritons (S) and guided waves (G) in a GaAs/$Al_{0.38}Ga_{0.65}As$ MQW. Inset: schematic diagram of the ATR stage. Interface phonons

Under certain conditions phonons can propagate along the interface between two different media that are in intimate contact, as for instance, in the case of thin epilayers on substrates, or in multilayered

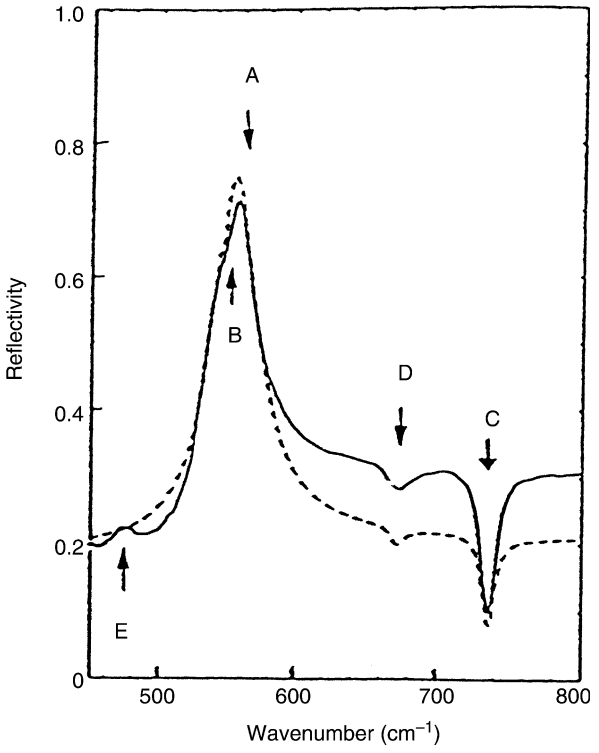

Figure 17 Far-infrared reflectivity of a GaN epilayer on a GaAs substrate at 290 K with dips due to a Brewster mode at C and a Berreman mode at D. Reproduced with permission from Mirjalili G, Parker TJ, Farjami Shayesteh S, Bulbul MM, Smith SRP, Cheng TS and Foxon CT (1998) Far infrared and Raman analysis of phonons and phonon interface modes in GaN epilayers on GaAs and GaP substrates. *Physical Review B* 57: 4656.

structures. There are two common sets of criteria for the existence of such interface modes. The first, leading to so-called Brewster modes, is when the numerator of the Fresnel reflection coefficient passes through zero due to impedance matching in the two media. The second, leading to a Berreman mode, is when the real part of the dielectric constant has a zero crossing in one of the media at a frequency where it is negative in the other medium. Both modes are observed as dips in the reflectivity. A reflection spectrum for a GaN epilayer on a GaAs substrate is shown in Figure 17. The two interface modes occur at frequencies close to the frequencies of GaN LO phonons; the Berreman mode is close to the GaN LO phonon frequency at the base of the GaN epilayer, which is shifted down by about 50 cm^{-1} from the bulk GaN value (735 cm^{-1}) due to disorder arising from the large lattice mismatch between the epilayer and the substrate. Both interface modes couple strongly to free carriers (i.e., plasmons) propagating normal to the interface, and thus act as useful probes of the structural and electronic properties of the epilayer. No other technique is available for probing the electronic properties of the epilayer for propagation normal to the layer.

Light Scattering

M Balkanski, Université Pierre et Marie Curie, Paris, France

© 2005, Elsevier Ltd. All Rights Reserved.

When a monochromatic light beam passes through a transparent medium, a small part of the light is scattered out of the incident direction with a change in frequency. The scattering processes are usually classified into three groups. The light scattering is named:

Brillouin scattering when the light is scattered with a small frequency shift that varies continuously with scattering angle.

Raman scattering when the light is scattered with a relatively large frequency shift that is independent of scattering angle. The possibility of observing a given transition, however, depends on the orientation of the crystal relative to the polarization of the incident light.

Rayleigh scattering when the light is scattered without frequency shift. In this case the scattering is elastic with the incident and scattered frequencies equal: $\omega_i = \omega_s$. Rayleigh scattering is particularly useful in the study of critical phenomena or aspects related to the size and polarizability of particles.

Brillouin Scattering

Brillouin scattering is caused by the interaction of light with the acoustic modes of vibration of the crystal. Consider an acoustic wave of frequency ω_a propagating with velocity $\pm v$ as shown in Figure 1. Light with incident frequency ω_i interacts strongly with acoustic waves satisfying the Bragg condition $\omega_a = 2\omega_i(v/c)n\sin(\theta/2)$, where n is the refractive index of the material and θ is the angle of deviation of the scattered beam. Since the acoustic waves are moving with velocity $\pm v$ the scattered light suffers a Doppler shift in frequency and exhibits a frequency doublet at the angle θ given by the Brillouin equation

$$\omega_i \pm \omega_a = \omega_i \pm 2\omega_i(v/c)n\sin(\theta/2)$$

In terms of the quantum picture, Brillouin scattering corresponds to scattering of incident photons of frequency ω_i and wavevector $\mathbf{k}_i$ into scattered photons of frequency ω_s and wavevector $\mathbf{k}_s$ with the emission or absorption of an acoustic phonon of frequency ω_a and wavevector $\mathbf{q}$. The predicted Brillouin spectrum is shown in Figure 2. It consists of Stokes ($\omega_s = \omega_i - \omega_a$) and anti-Stokes ($\omega_s = \omega_i + \omega_a$) components corresponding to phonon emission and absorption, respectively.

The frequency shift $|\omega_i - \omega_s|$ for a well-defined scattering angle θ directly gives the acoustic phonon frequency and velocity. The width Γ of the Brillouin component of the spectrum is a measure of the damping or attenuation of the wave.

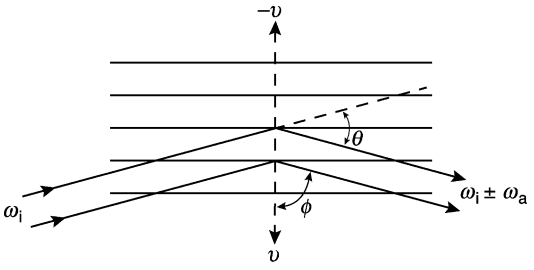

Figure 1 Light scattering at angle ϕ and Bragg reflection at angle θ by moving thermal waves.

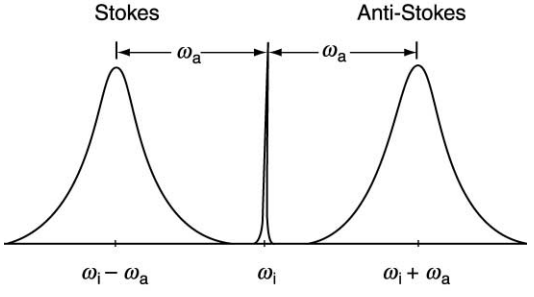

Figure 2 Schematic diagram of a Brillouin spectrum.

Raman Scattering

The essential difference between Brillouin and Raman scattering is that in Raman scattering the incident light beam is scattered with relatively large frequency shift independent of the scattering angle. The same basic considerations apply to Raman scattering that apply to Brillouin scattering. The Raman spectrum has Stokes and anti-Stokes branches corresponding to the emission and absorption, respectively, of an elementary excitation. A variety of elementary excitations are important. They include optical phonons and, in the case of magnetic materials, magnons. Also of interest are electronic excitations such as intraband single-particle excitations, interband excitations, and collective excitations (plasmons).

Raman Scattering by Phonons

An inelastic light scattering event involves the destruction of a photon of frequency ω_i incident from a light source, the creation of a scattered photon of frequency ω_s and the creation or destruction of an optical phonon of frequency ω_o.

Destruction of a photon involves interaction of the radiation field with matter by which a pair of free carriers is created in the semiconductor corresponding to a virtual transition between the valence and conduction bands. The excited state, free electron in the conduction band, interacts with the lattice via the optical deformation potential. This interaction results in the creation or annihilation of an optical phonon of frequency ω_s. When the resulting process corresponds to the creation emission of a phonon, the frequency of the scattered photon is $\omega_s = \omega_i - \omega_a$ and is referred to as the Stokes component of the spectrum. When the process is the annihilation or absorption of a phonon the scattered frequency is $\omega_s = \omega_i + \omega_a$, referred to as the anti-Stokes component.

These two first-order scattering events can be described in terms of Feynman diagrams as shown in Figure 3.

Considering these elementary processes one can calculate, using time-dependent perturbation theory, the Raman amplitude and hence the differential scattering cross-section. The remarkable feature here is that for incident frequencies approaching the frequencies of an electronic excited state of the material the Raman amplitude diverges. This leads to the phenomenon of resonant Raman scattering.

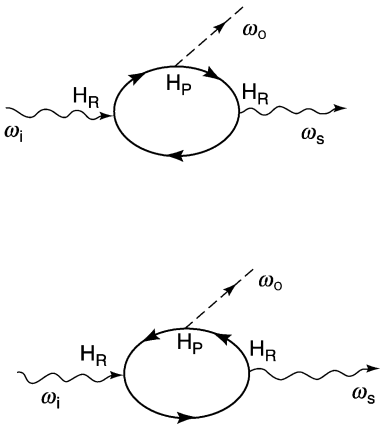

Figure 3 Feynman diagrams for two first-order scattering events.

The Raman scattering efficiency, which is the scattering cross-section per illuminated area can be calculated numerically. Numerical estimates give efficiencies typically of order 10^{-6} or 10^{-7}.

In polar semiconductors the macroscopic electric field leads to an additional contribution to the scattering cross-section for the longitudinal optical (LO) phonon modes. The macroscopic field is a consequence of the Coulomb field of the ionic charges and gives rise to an electron–phonon interaction.

There is no simple relationship between the scattering intensities for transverse optical (TO) and LO phonons in polar semiconductors.

When the probing frequency coincides with the transverse optical mode frequency, i.e., for the regime $cq \cong \omega_{TO}$ (where c is the light velocity, q the photon wavevector and ω_{TO} the transverse optical phonon frequency) in polar semiconductors it is necessary to take into account the polariton nature of the coupled photon–TO-phonon modes and their associated macroscopic electrical field. The dispersion relation of the coupled photon–TO mode, called a polariton, consists of two branches: an upper branch ω_+, in which the electro-optical contribution dominates, and the lower branch ω_-, which contains essentially the mechanical contribution. This leads to a contribution to the Raman amplitude from both mechanical and electro-optical origins. An exception occurs for the lower polariton branch with $\omega = \omega_{TO}$; then the electro-optic contribution is very small compared to the mechanical contribution. If $cq \gg \omega_{TO}$ as in the upper polariton branch, destructive interference between the mechanical and electro-optic contributions can occur.

Selection Rules in Raman Scattering

Not all elementary excitations in semiconductors scatter light. The Raman active modes are determined by selection rules established using group-theoretical methods. The various normal modes in a given crystal correspond to various symmetries of the vibrations of the atoms in the crystal and are characterized by the irreducible representations of the space group of the crystal lattice. One can show that a normal mode can participate in a first-order Raman transition if and only if its irreducible representation is the same as one of the irreducible representations that occur in the reduction of the representation of the Raman tensor.

An important result of group theory is the rule of mutual exclusion which states that, in crystals with a center of inversion, excitations that are active in the first-order infrared spectrum are inactive in the first-order Raman spectrum, and conversely, excitations that are active in the first-order Raman spectrum are inactive in the first-order infrared spectrum. In particular, the first-order spectra due to optical phonons in NaCI are infrared active, but Raman inactive, whereas in Si they are infrared inactive, but Raman active. This difference is related to the fact that each atomic site in NaCI is a center of inversion and the active optical phonons have odd parity whereas each midpoint between two nearest-neighbor atomic sites in Si is a center of inversion and the active optical phonons have even parity.

In a crystal with the zinc blend structure, there is no center of inversion, and the crystal is both infrared and Raman active. The only non-vanishing elements of the Raman tensor $R(\hat{e})$ with $\hat{e} \| z$ are the xy and yx elements. To observe the Raman effect of an LO phonon propagating in the z-direction, one can arrange the polarization of the incident light parallel to the x-axis and observe the scattered light with its polarization parallel to the y-axis or vice versa. An analogous set of constraints applies to TO phonons. A typical spectrum is illustrated in Figure 4.

For higher-order Raman processes in which several phonons participate, it is the product of the irreducible representations of the phonons involved that must be the same as the irreducible representation of the Raman tensor.

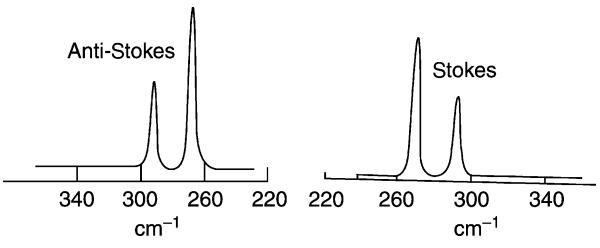

Figure 4 Raman spectrum for optical phonons.

Geometrical Aspects of First-Order Raman Scattering

The observation of light scattering by optical phonons in transparent crystals is usually done in a geometry in which the linearly polarized incident light beam is directed along, say, the x-axis and the scattered beam is observed along the y-axis (see Figure 5). When the crystal is not transparent, as is often the case in semiconductors, the observation is made in the backscattering geometry in which the scattered beam is observed in the opposite direction to the incident beam.

The scattering geometry affects the range of phonon wavevectors that is accessible in first-order Raman scattering. The condition of wavevector conservation is

$$\mathbf{K}_i - \mathbf{K}_s = \pm\mathbf{q}$$

where $\mathbf{q}$ is the phonon wavevector and the plus (minus) sign refers to the Stokes (anti-Stokes) process. The Stokes geometry is shown in Figure 6 and satisfies the following relation:

$$q^2 = k_i^2 + k_s^2 - 2k_i\, k_s \cos\theta$$

Forward scattering is characterized by $\theta = 0$ and a minimum value of q given, for isotropic media, by

$$q_{min} = \frac{n(\omega_i)\,\omega_i - n(\omega_s)\omega_s}{c}$$

where $n(\omega_i)$ and $n(\omega_s)$ are the refractive indices of the crystal for the incident and scattered light, respectively, and $k_{i(s)} = n(\omega_{i(s)})\omega_{i(s)}/c$.

Back scattering is characterized by the maximum value of q when $\theta = 180°$ and is given by

$$q_{max} = \frac{n(\omega_i)\omega_i - n(\omega_s)\omega_s}{c}$$

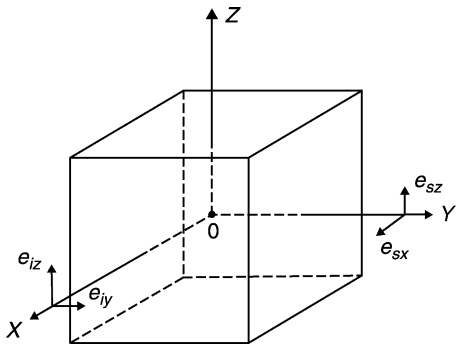

Figure 5 Geometry for light-scattering experiments in transparent crystals.

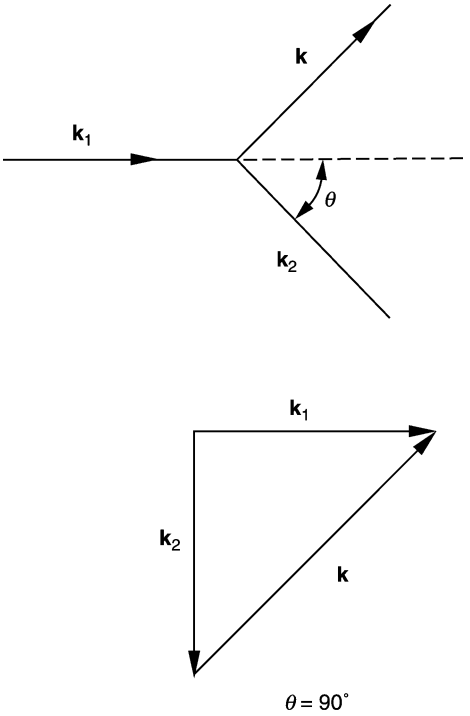

Figure 6 Diagram for Stokes processes.

For typical light-scattering experiments in the visible region the range of the incident wavevector is $0 < k_i < 10^6\ \mathrm{cm}^{-1}$. This implies that for first-order scattering processes the accessible range of $\mathbf{q}$ under conditions of wavevector conservation is small compared to a nonzero reciprocal lattice wavevector. Light-scattering experiments yield the frequencies of optical modes at essentially the center of the Brillouin zone.

The energy and momentum conservation rules have to be modified when the lifetime of the crystal excitations are strongly limited by their decay into other crystal excitations. Momentum conservation breaks down in imperfect crystals, in solids lacking translational symmetry like amorphous materials, and in crystals which are opaque to incident and scattered light.

In those cases where the incident and scattered waves are damped inside the scattering volume, such as occur in small-gap semiconductors that are opaque at the light frequencies involved, $\mathbf{k}_i$ and $\mathbf{k}_s$ are complex. The inelastic scattering is due to excitations having a range of wavevector

$$\Delta q = |\mathrm{Im}\,\mathbf{k}_i| + |\mathrm{Im}\,\mathbf{k}_s|$$

about $\mathbf{q} = \mathrm{Re}(\mathbf{k}_i - \mathbf{k}_s)$. Effects associated with such a wavevector uncertainty have been reported in

Raman scattering spectra of III–V semiconductor compounds.

Second-Order Raman Scattering

Second-order Raman scattering involves two phonons rather than a single phonon as in first-order scattering. The possible second-order processes are the following: two phonons may be created, giving a Stokes component in the scattered light, or one is created and the other destroyed, giving a Stokes or anti-Stokes component, or both may be destroyed giving an anti-Stokes component. For each of these cases there are the possibilities of a pair of first-order electron–phonon interactions or a single second-order electron–phonon interaction.

In the case of second-order Raman scattering the wavevector conservation condition is $\mathbf{q}_1 \pm \mathbf{q}_2 \cong 0$, where $\mathbf{q}_1$ and $\mathbf{q}_2$ are the wavevectors of the phonons involved. This condition places no restriction on the magnitudes of the individual wavevectors, other than $|q_1| \cong |q_2|$, which is in contrast to first-order scattering where $q \cong 0$.

The possible phonon frequency pairings associated with second-order processes are $\omega_1 + \omega_2$ (combination band), $\omega_1 - \omega_2$ (difference band), and $2\omega_1$, (overtone band). The second-order scattering spectrum covers a broad range of frequencies. The overtone spectrum provides a measure of the phonon density of states.

Resonant Light Scattering

General Formulation

Resonant Raman scattering occurs when the incident or scattered photon energy is close to the energy of an intermediate electronic state relative to the ground electronic state. Certain terms in the Raman amplitude then diverge leading to a very large scattering cross-section. Divergences occur in the Stokes spectrum when $h\omega_i = h\omega_a$, and $h\omega_s = h\omega_b$: the photon energies *resonate* with the excitation energies of the intermediate states *a* or *b*. If *a* and *b* are the same state, resonance occurs nearly simultaneously for both ω_i and ω_s, and gives rise to a particularly strong enhancement of the scattering efficiency. It is thus clear that the resonance phenomenon is specific to the nature of the intermediate state, and its investigation leads to basic information concerning the electronic states of the system. We shall now examine the resonance behavior in several cases where the intermediate states are carrier Bloch states, free excitons, or bound excitons.

Resonance at the Fundamental Bandgap

The divergent behavior of the Raman amplitude is associated with the factor $(h\omega_i - E_g)^{-1}$ where E_g is the lowest direct bandgap of the material.

Resonance at Free Exciton States

The Raman intensity as a function of the incident photon energy has a Lorentzian line shape in the range of a single intermediate state. It is centered at the resonance frequency and has a width determined by the lifetime of the intermediate state. The distinction between scattering at resonance and scattering off resonance in the wings of the Lorentzian is that at resonance the intensity is determined by the exciton lifetime, whereas off resonance it is determined by the frequency separation from resonance. Since in many instances excitons have very long lifetimes, they can lead to a very large Raman cross-section at resonance.

Resonance at Bound Exciton States

Scattering induced by the presence of impurities involving bound exciton states has the following essential features: (a) observation of sharp resonance at the energies of the bound exciton which form discrete levels below the free exciton resonance; (b) dependence upon impurity concentration; (c) involvement of LO phonons of wavevector of the order of the inverse of the impurity state radius. Resonance at bound exciton energies has been observed in impurity-induced resonant Raman scattering by LO phonons in CdS. The resonance is centered at the absorption peak for the impurity state and has approximately Lorentzian shape. If the impurity gives rise to a localized vibrational mode, bound exciton resonance in Raman scattering due to the local mode can occur.

Anharmonic Effects on Raman Spectra

In a perfect crystal whose vibrations are harmonic and which is transparent to the incident and scattered light, the Raman lineshape is a delta function centered on the optical phonon frequency. Experimentally one finds that even in crystals of very high quality, the Raman line is broadened into a roughly Lorentzian shape with a width that increases with increasing temperature. This width can be attributed to anharmonic terms in the vibrational Hamiltonian.

The temperature dependence of the line width is determined by the phonon occupation factors. As the temperature approaches zero, the phonon

occupation factor approaches zero also, and the width approaches the value due to the zero-point motion of the nuclei. At temperatures above the Debye temperature, the width due to cubic anharmonicity becomes proportional to T. Quartic anharmonicity imparts a T^2 dependence to the width which becomes significant at very high temperatures.

In addition to line broadening, anharmonicity causes a shift of the frequency of peak intensity to lower values as the temperature increases. Contributions to the shift proportional to T and T^2 arise in the high-temperature regime from cubic and quartic anharmonicity, respectively.

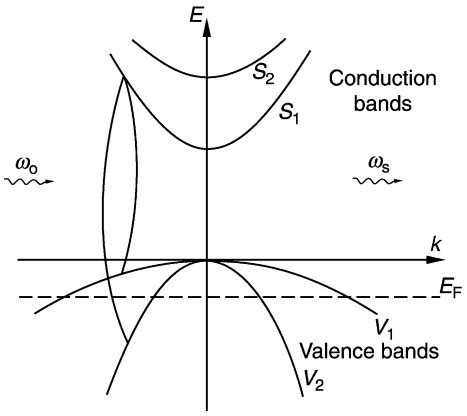

Figure 7 Electronic transitions occurring in intervalence band scattering.

Light Scattering due to Electronic Excitations

Light Scattering by Plasmons

Plasmons are similar to LO phonons in that they have a macroscopic electric field associated with them. The field modulates the electric susceptibility and gives rise to Raman scattering. The difference in frequency of the incident and scattered light is equal to the plasma frequency ω_p specified by $\omega_p = e^2 n/\varepsilon_0 \varepsilon_\infty m^*$, where n is the electron concentration, m^* is their effective mass, and ε^∞ is the high-frequency dielectric constant.

When the plasma frequency is close to the LO phonon frequency, there is a plasmon–phonon interaction via the macroscopic electric fields that leads to coupled modes and forces the frequencies apart.

Light Scattering Associated with Interband Transitions

The plasmons dealt with in the preceding section are an intraband type of excitation. Also of interest are interband transitions in which a carrier undergoes a transition from one band to a different band during the scattering process. An example is provided by p-type silicon in which an electron makes a transition from an occupied state in the light-hole band to an unoccupied state in the heavy-hole band via the conduction band as shown in Figure 7.

For the case of isotropic bands the scattering efficiency spectrum at 0 K has sharp edges. If the anisotropy of the valence bands is taken into account, the sharp edges of the spectrum are smoothed out.

The experimental Raman spectrum for p-type Si exhibits a broad continuum due to the electronic transitions but in the same spectral range there are also Raman active optical phonons which superpose on the electronic continuum and distort it. The resulting distortion of the spectrum is associated with resonant interference that occurs between the discrete phonon line and the electronic continuum.

SEMICONDUCTOR PHYSICS

Polarons

J T Devreese, Universiteit Antwerpen, Antwerp, Belgium

© 2005, Elsevier Ltd. All Rights Reserved.

The Polaron Concept

If an electron (or hole) is placed in a polarizable medium (like an ionic crystal or a polar semiconductor), it induces a deformation of polarization field around itself. On the other hand, the electron is attracted to the potential well of this disturbed polarization field. Thus, a feedback loop between the electron and the polarization field arises, which leads to a highly correlated state of the charge carrier and the polarization field. A conduction electron (or hole) together with its self-induced polarization in an ionic crystal or in a polar semiconductor forms a quasiparticle, which is called a polaron. The polaron concept was introduced by Landau in 1933.

The physical properties of the polaron differ from those of the band carrier. In particular, the polaron is characterized by its binding (or self-) energy E_0, effective mass m^* and by its response to external electric and magnetic fields (e.g., dc mobility and optical absorption coefficient).

If the spatial extension of the polaron is large compared to the lattice parameters of the solid, the latter can be treated as a polarizable continuum. This is the case of a 'large polaron', to which most of this article is confined.

The polaron characteristics are determined by the coupling between an electron and the long-wavelength longitudinal optical (LO) phonons. The strength of this coupling is expressed in terms of the constant introduced by Fröhlich:

$$\alpha = \frac{e^2}{\hbar c}\sqrt{\frac{m_b c^2}{2\hbar\omega_{LO}}}\left(\frac{1}{\varepsilon_\infty} - \frac{1}{\varepsilon_0}\right) \qquad [1]$$

In this definition, ω_{LO} is the frequency of LO phonons, c is the velocity of light, and ε_∞ and ε_0 are, respectively, the electronic and the static dielectric constant of the polar crystal.

In order to find the coupling constant according to eqn [1], it is crucial to know the electron (hole) band mass m_b. This unknown parameter can, in principle, be determined from experiment. However, in ionic crystals and polar semiconductors, experiment measures the polaron effective mass m^* rather than the band mass, because of the polaron effect. The problem of determining the band mass is therefore far from trivial and should be tackled on the basis of the results of polaron theory. In Table 1 the coupling constants are indicated for a number of crystals.

Landau and Pekar were the first to investigate the self-energy and the effective mass of the strong-coupling polaron, when $\alpha \gg 1$. As seen from Table 1, in substances with large values of the electron–phonon coupling constant (like alkali halides, TlBr, CdF_2, $SrTiO_3$) α ranges between 2.5 and 4.5. Though, strictly speaking, polarons in such materials are of intermediate coupling, their properties can be approached within the strong-coupling approximation.

The cases when $\alpha \ll 1$ (like InSb, InAs, GaAs) are referred to as the weak-coupling regime. Polarons in many other substances with $\alpha < 1$ (e.g., GaP, CdTe, ZnSe, CdSe, CdS, CdO) are well described in the weak-coupling approximation.

In the weak-coupling regime, the states of the polaron can be imagined as those of a band carrier perturbed by the electron–phonon interaction. Fröhlich provided in 1954 the first weak-coupling perturbation theory results for the polaron characteristics:

$$E_0 = -\alpha\hbar\omega_{LO} \qquad [2]$$

$$m^* = \frac{m_b}{1 - \alpha/6} \qquad [3]$$

Feynman formulated the polaron problem in the Lagrangian (path integral) form of quantum mechanics and obtained an upper bound for the polaron self-energy at all values of the α, which at weak and strong coupling gave accurate limits. Over the years the Feynman all-coupling model

Table 1 Electron–phonon coupling constants

Material	α	*Material*	α
InSb	0.02	AgCl	1.8
InAs	0.052	KI	2.5
GaAs	0.068	TlBr	2.55
GaP	0.201	KBr	3.05
CdTe	0.286	RbI	3.16
ZnSe	0.43	CdF_2	3.2
CdSe	0.49	KCl	3.5
CdS	0.52	CsI	3.67
CdO	0.74	RbCl	3.81
AgBr	1.6	$SrTiO_3$	4.5

for the polaron has been proven to be in many respects the most successful approach to the polaron problem.

Optical Properties and Internal Structure of Polarons

Optical Absorption of Polarons at Weak Coupling

At zero temperature and in the weak-coupling limit, the optical absorption is due to the following elementary polaron scattering process, schematically shown in Figure 1. An incoming photon is absorbed by a polaron. The polaron emits a phonon during the absorption process and takes recoil energy from the incident light. At zero temperature, the absorption coefficient for absorption of light with frequency Ω can be expressed in terms of elementary functions in two limiting cases: in the region of comparatively low frequencies $(\hbar(\Omega - \omega_{LO})/\zeta \ll 1)$

$$\Gamma(\omega)=\frac{1}{\varepsilon_0 nc}\frac{2^{1/2}N^{2/3}\alpha}{(3\pi^2)^{1/3}}\frac{e^2}{(\hbar m_b\omega_{LO})^{1/2}}\frac{\omega-1}{\omega^3}\Theta(\omega-1) \quad [4]$$

and in the high-frequency region $(\hbar(\Omega-\omega_{LO})/\zeta \gg 1)$

$$\Gamma(\omega)=\frac{1}{\varepsilon_0 nc}\frac{2Ne^2\alpha}{3m_b\omega_{LO}}\frac{(\omega-1)^{1/2}}{\omega^3}\Theta(\omega-1) \quad [5]$$

Here $\omega=\Omega/\omega_{LO}$, ε_0 is the dielectric permittivity of the vacuum, n is the refractive index of the medium, N is the concentration of polarons, and ζ is the Fermi level for electrons. The step function

$$\Theta(\omega-1)=\begin{cases}1 & \text{if } \omega>1\\ 0 & \text{if } \omega<1\end{cases} \quad [6]$$

reflects the fact that at zero temperature absorption of light accompanied by emission of a phonon can occur only if the energy of a photon is larger than that of a phonon ($\omega>1$). In the weak-coupling limit, according to eqn [4], the absorption spectrum consists of a one-phonon line.

Experimentally, the one-phonon line has been clearly seen for free polarons in the infrared absorption spectra of CdO-films (see Figure 2). In CdO, which is a weakly polar material with $\alpha \approx 0.74$, the optical absorption band is observed in the spectral region between 6 and 20 μm (above the LO phonon frequency). As seen from Figure 2, this optical absorption band can be attributed to the weak-coupling polaron absorption as described by eqn [4].

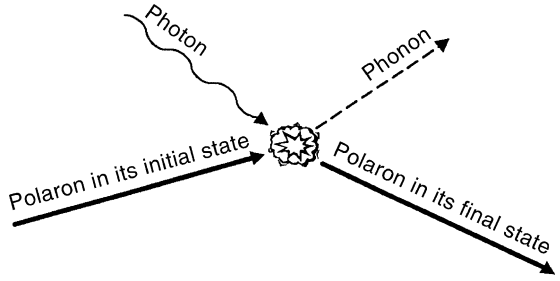

Figure 1 The elementary polaron scattering process leading to absorption of an incoming photon and to generation of an outgoing phonon.

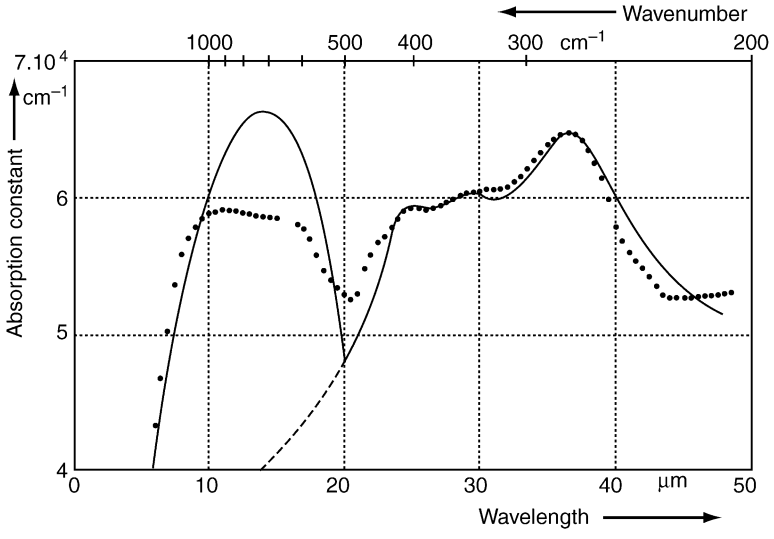

Figure 2 Optical absorption spectrum of a CdO film with the carrier concentration $N = 5.9 \times 10^{19}$ cm^{-3} at $T = 300$ K. The theoretical results are shown with (solid curves) and without (dashed curves) the polaron contribution of eqn [4], and compared to the experimental data (solid dots). (Reproduced with permission from Finkenrath H, Uhle N and Waidelich W (1969) The influence of phonons and polarons on the infrared absorption of cadmium oxide[*1]. *Solid State Communications* 7: 11–14.)

With strengthening coupling, it becomes possible that absorption of a photon is accompanied by emission of two, three, …, K phonons, thus giving rise to two-, three-, …, K-phonon sub-bands in the optical absorption spectra. At high temperatures, absorption of a photon can be accompanied not only by emission, but also by absorption of one or more phonons.

Optical Absorption of Polarons at Arbitrary Coupling

The theoretical absorption spectrum of a single large polaron (at all electron–phonon coupling strengths) is given by the expression

$$\Gamma(\omega) = \frac{1}{n\varepsilon_0 c} \frac{\mathrm{Im}\Sigma(\omega)}{[\omega - \mathrm{Re}\Sigma(\omega)]^2 + [\mathrm{Im}\Sigma(\omega)]^2} \qquad [7]$$

The so-called memory function $\Sigma(\omega)$ contains the dynamics of the polaron and depends on α and ω. This function is related to the impedance function $Z(\omega)$ of the polaron through $-\mathrm{i}Z(\omega) = \omega - \Sigma(\omega)$.

Optical Absorption of Polarons at Strong Coupling

The absorption of light by free large polarons was treated by Kartheuser, Evrard and Devreese using the adiabatic strong-coupling method by Landau and Pekar. The polaron ground state in this scheme has the energy

$$E_0 = -\frac{\alpha^2}{3\pi}\hbar\omega_{\mathrm{LO}} = -0.106\alpha^2\hbar\omega_{\mathrm{LO}} \qquad [8]$$

If the lattice polarization is allowed to relax or adapt to the electronic distribution of the excited electron (which itself then adapts its wavefunction to the new potential, etc., leading to a self-consistent final state), the so-called relaxed excited state (RES) results. Its energy is

$$E_{\mathrm{RES}} = -0.041\alpha^2\hbar\omega_{\mathrm{LO}} \qquad [9]$$

It was argued by Kartheuser, Evrard and Devreese, that for a sufficiently large α ($\alpha > 3$), the (first) RES of a polaron is a stable state, which can participate in optical absorption transitions. This idea was important in order to understand the optical absorption spectrum in the strong-coupling regime. In particular, the following scenario of a transition, which leads to a zero-phonon peak in the absorption by strong-coupling polaron, can be suggested. If the frequency of a photon is equal to

$$\Omega_{\mathrm{RES}} \equiv \frac{E_{\mathrm{RES}} - E_0}{\hbar} = 0.065\alpha^2\omega_{\mathrm{LO}} \qquad [10]$$

then the electron goes from the ground state (following the analogy with the hydrogen atom, let us call it '1s') to an excited state ('2p'), while the lattice polarization in the final state is adapted to the '2p' state of the polaron.

Each RES of the polaron can be accompanied by 1, 2, 3, … free optical phonons in the lattice. Such states are called scattering states (ScS). They are shown in Figure 3. Starting with the photon energy

$$\Omega_{\mathrm{RES}} + \omega_{\mathrm{LO}} \qquad [11]$$

a transition of the polaron towards the first ScS, belonging to the RES, becomes possible. In the course of this transition, while absorbing a photon, the polaron goes from the ground state to the RES with emission of one extra phonon. This process is called one-phonon sideband absorption.

The one-, two-, …, K-phonon sidebands give rise to the broad structure of the absorption coefficient. These transitions occur without lattice relaxation. The (unstable) polaron state, in which the lattice polarization corresponds to the electron ground state, while the electron is excited ('a frozen lattice'), is referred to as the *Franck–Condon* (FC) state of a polaron. Within the adiabatic approach, the energy of the lowest FC state is

$$E_{\mathrm{FC}} = \frac{\alpha^2}{9\pi}\hbar\omega_{\mathrm{LO}} = 0.035\alpha^2\hbar\omega_{\mathrm{LO}} \qquad [12]$$

The superposition of the one-, two-, …, K-phonon sidebands is centered at the FC transition frequency

$$\Omega_{\mathrm{FC}} \equiv \frac{E_{\mathrm{FC}} - E_0}{\hbar} = 0.141\alpha^2\omega_{\mathrm{LO}} \qquad [13]$$

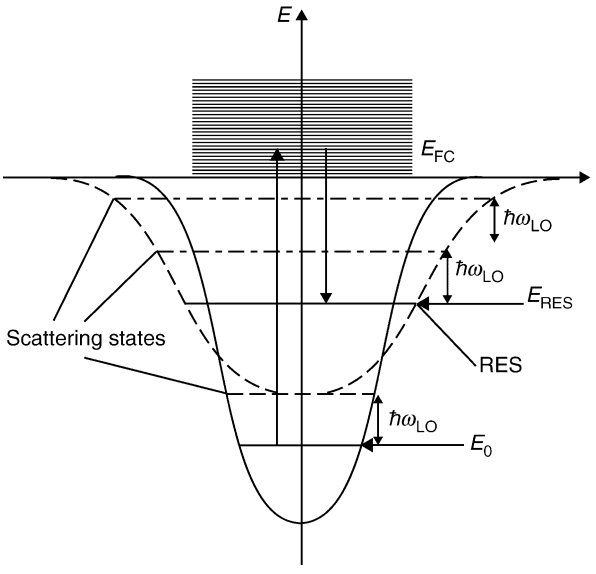

Figure 3 Internal excitations of a polaron at strong coupling: E_0 – the ground state, E_{RES} – the (first) relaxed excited state; the Franck–Condon states (E_{FC}) are shown with a set of horizontal lines above the zero energy. In fact, both the Franck–Condon states and the relaxed excited states lie in the continuum and, strictly speaking, are resonances.

The optical absorption spectrum at strong coupling is, thus, characterized by the following features.

(a) There is an intense absorption peak ('zero-phonon line'), which corresponds to a transition from the ground state to the first RES at Ω_{RES}.
(b) At $\Omega_{RES} + 1$, a phonon sideband structure appears (namely, a K-phonon sideband at $\Omega_{RES} + K$). The maximum of this structure occurs at the FC transition frequency Ω_{FC}.

The qualitative behavior predicted by Kartheuser, Evrard and Devreese, namely, an intense zero-phonon (RES) line with a broader sideband at the high-frequency side, was revealed using a general all-coupling expression for the optical absorption coefficient [7] at $\alpha = 5, 6, 7$.

Internal Structure of Polarons at Arbitrary Coupling

The optical absorption spectra calculated according to the theory of Devreese *et al.* are displayed in Figure 4 for values of α in the range from 1 to 6.

The absorption spectrum for $\alpha = 1$ consists of a one-phonon line, similar to the weak-coupling result. The absorption peak for $\alpha = 3$ might correspond to a one-phonon peak at this intermediate coupling. It was also argued that part of the oscillator strength in the absorption for $\alpha = 3$ is due to lattice relaxation in the final states, be it to a smaller extent than for $\alpha = 5$.

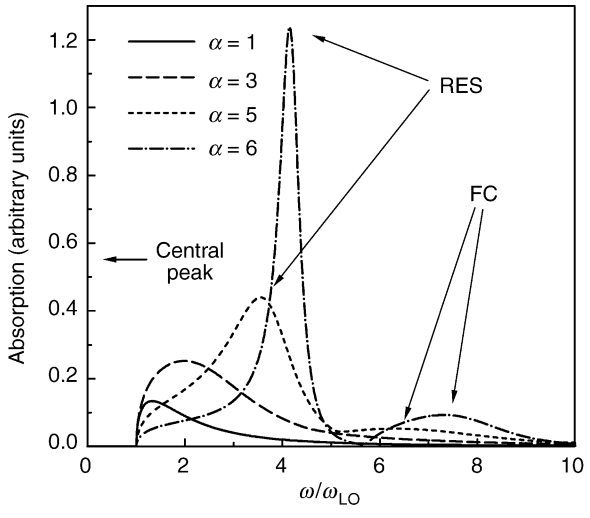

Figure 4 Polaron optical absorption spectra at zero temperature, calculated within the path integral method (according to eqns [11a], [12], [13] of the paper (Devreese JT, De Sitter J and Goovaerts M (1972) Optical absorption of polarons in the Feynman–Hellwarth–Iddings–Platzman approximation. *Physical Review B* 5: 2367–2381)) for different values of the electron–phonon coupling constant α. The peaks are labeled in the picture according to their physical origin as discussed in the text. A δ-like central peak is schematically shown by a vertical line.

It is remarkable that from [7] the three different kinds of polaron excitations appear in the calculated optical absorption spectra for polarons at $\alpha \geq 5$:

- scattering states where, e.g., one real phonon is excited (the structure starting at $\omega = 1$);
- relaxed excited state (RES);
- Franck–Condon (FC) states.

Besides that, at zero temperature, the optical absorption spectrum for one polaron contains a central peak [$\sim\delta(\omega)$] at the origin. For nonzero temperature, this central peak smears out and the optical absorption spectrum consists of both a broad envelope and an anomalous Drude-type low-frequency component.

For example, in Figure 4 the main peak of optical absorption for $\alpha = 5$ at $\omega = 3.51$ is interpreted as due to transitions to RES. The shoulder at the low-frequency side of the main peak is attributed to one-phonon transitions to scattering states. The structure centered at about $\omega = 6.3$ is attributed to a FC band. As seen from Figure 4, when increasing the electron–phonon coupling constant to $\alpha = 6$, the RES peak at $\omega = 4.3$ becomes very intense compared with the FC peak centered at $\omega = 7.5$.

The free-carrier polaron effects were revealed through measurements of optical constants, of cyclotron resonance and of mobility in semiconductors and insulating photoconductors. Experimentally, only the scattering states have been seen for free polarons. However, the full structure of eqn [7] has been revealed through cyclotron resonance measurements.

Magneto-absorption of Polarons

Polaron Cyclotron Resonance

A polaron in a magnetic field is referred to as a *magnetopolaron*. The most powerful technique to study the electron–phonon coupling in semiconductors is cyclotron resonance. Changing the magnetic field B allows one to vary the cyclotron frequency $\omega_c = eB/m_b c$. When it is brought closer to resonance with the phonon frequency ω_{LO}, a strongly renormalized magnetopolaron state is formed. This results in a splitting of the cyclotron resonance, which is a measure of the electron–phonon (polaron) coupling constant α.

A theory of the polaron effects in cyclotron resonance was proposed by Larsen. In particular, the variational approach of Larsen is based on an intermediate-coupling theory to calculate the energy levels (modified Landau levels) of a polaron in a

magnetic field. The polaron mass is then defined from the energy differences between the polaron (Landau-) energy levels.

A rigorous way to find the polaron cyclotron mass is to calculate the magneto-optical absorption spectrum of the polaron (the quantity which is actually measured) and to define the polaron mass, in the same way as the experimentalists do, from the peak positions in the spectrum. The magneto-optical absorption of polarons for all α and ω_c at $T = 0$ was calculated by Peeters and Devreese. They extended the memory-function formalism described above to study the response of a polaron in a magnetic field. The magneto-absorption was then obtained from

$$\lim_{\varepsilon \to 0} \mathrm{Re} \frac{1}{z - \omega_c - \Sigma(z)} \qquad z = \omega + \mathrm{i}\varepsilon \qquad [14]$$

where $\omega_c = eB/m_b$ is the cyclotron frequency for a rigid-lattice band mass m_b, and $\Sigma(z)$ is the memory function, which takes into account all the polaron internal states as well as all the Landau levels and depends on the coupling constant α and on the magnetic field. The explicit results for $\Sigma(z)$ depend on the optimal parameters of the anisotropic Feynman polaron model, which are found by a variational calculation of the polaron ground-state energy.

At $T = 0$ and when $\omega < 1$, it follows that $\mathrm{Im}\Sigma(\omega) = 0$. According to eqn [14], the position of the cyclotron resonance line is determined by the equation $\omega - \omega_c - \Sigma(\omega) = 0$. If solutions of this equation are denoted as $\omega = \omega_c^*$ then the polaron cyclotron mass m_p^* is calculated from the relation $\omega_c^* = eB/m_p^*$.

Cyclotron Resonance of Polarons in Silver Halides

In pioneering experimental studies, Brown and coworkers have combined mobility experiments and cyclotron resonance measurements to clearly demonstrate the polaron effect in AgBr. From a theoretical plot of polaron mobility versus band mass compared to experimental Hall mobility data at a given temperature, they estimate the band mass. This allows them to calculate α and the polaron mass m^*. This value of m^* can then be compared to the measured cyclotron mass in order to test the polaron theory. For AgBr, the experimental value $m^*/m_e = 0.27 \pm 0.01$ obtained from the cyclotron resonance at millimeter wave frequencies and at 18 K is shown to agree well with the value $m^*/m_e = 0.27 \pm 0.05$ determined by comparison of mobility experiment and theory.

Precise cyclotron mass measurements in AgBr and AgCl covered the range from zero magnetic field to 16 T (see Figure 5). Several polaron theories were compared in analyzing these experimental data. It should be pointed out that the weak-coupling theories (Rayleigh–Schrödinger perturbation theory, Wigner–Brillouin and its improvements) fail (and are all off by at least 20% at 16 T) to describe the

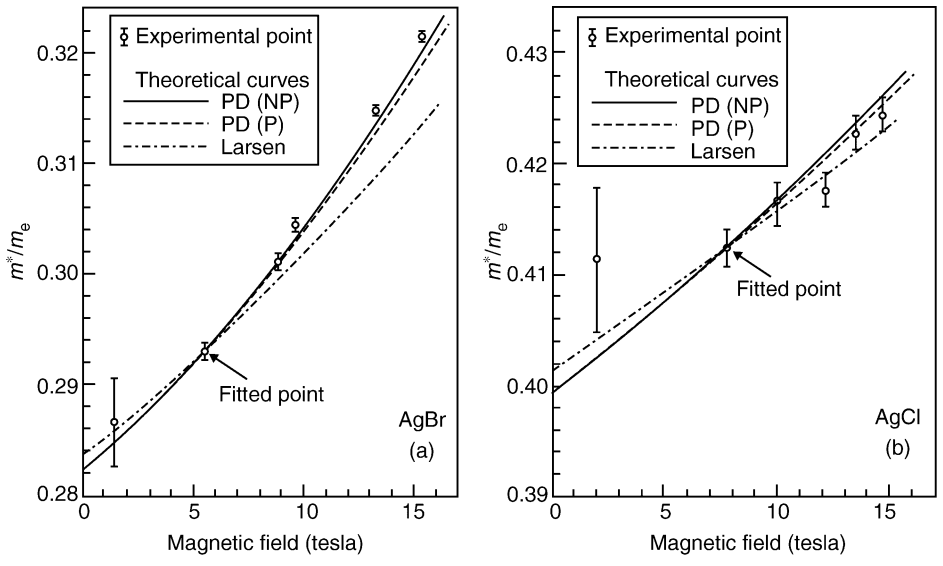

Figure 5 The polaron cyclotron mass in AgBr (a) and in AgCl (b): comparison of experiment and theory. Larsen: (Larsen D (1974) *Journal of Physics C* 7: 2877–2889); PD: (Peeters FM and Devreese JT (1986) *Physical Review B* 34: 7246–7259) (P) – with parabolic band, (NP) – with corrections of the two-band Kane model. In each case the band mass was adjusted to fit the experimental point at 525 GHz. experimental data for the silver halides. The variational approach by Larsen underestimates the polaron cyclotron mass by 2% at 15.3 T. It turns out that the magneto-absorption calculated by Peeters and Devreese leads to the best quantitative agreement between theory and experiment as was analyzed for AgBr and AgCl. This analysis provides a clear confirmation of the Fröhlich description of the polaron in the case where weak-coupling approximations are adequate.

Cyclotron Resonance of Polarons in CdTe

The early infrared transmission study of hydrogen-like shallow donor impurity states in *n*-CdTe was reported by Cohn, Larsen and Lax (see Figure 6). By studying the Zeeman splitting of the $(1s \rightarrow 2p, m = \pm 1)$ transition in the Faraday configuration at magnetic fields up to ~160 kOe, they performed the first quantitative determination of polaron shifts of the energy levels of a bound electron. The experimental data were shown to be in good agreement with the weak-coupling theory of the polaron Zeeman effect. In this comparison, however, the value $\alpha = 0.4$ was used instead of $\alpha = 0.286$, which comes from the definition [1]. Similarly, the value $\alpha \sim 0.4$ was suggested to explain the measured variation of the cyclotron mass with magnetic field in CdTe. This discrepancy gave rise to a discussion where important contributions have been, in particular, due to Harper and Zawadzki.

Grynberg *et al.* applied the far-infrared photoconductivity technique to study the energy spectrum of shallow In donors in CdTe layers and obtained experimental data over the energy range relevant to study the magnetopolaron effect, as shown in Figure 7. An overall good agreement is found between experiment and the theoretical approach, where the electron–phonon interaction is treated within a second-order improved Wigner–Brillouin perturbation theory and a variational calculation is performed for the lowest-lying donor states ($1s$, $2p^{\pm}$, $2s$, $2p_z$, $3d^{-2}$, $4f^{-3}$). It is to be stressed that this agreement is achieved with the coupling constant $\alpha = 0.286$ as follows from eqn [1] with the known material parameters of CdTe.

Polarons in the Layered Compound InSe and in Superlattices

Nicholas *et al.* provided a clear demonstration of the polaron coupling by the cyclotron resonance in a two-dimensional electron gas (2DEG), which naturally occurs in the polar semiconductor InSe. One clearly sees, over a wide range of magnetic fields ($B = 18-34$ T), the two distinct magnetopolaron branches separated by as much as 11 meV ($\sim 0.4\omega_{LO}$) at resonance (Figure 8). The lines show the results of theoretical calculations for coupling to the LO phonon in bulk (3D), sheet (2D) and after correction for the quasi-2D systems at $\alpha = 0.29$ (for motion perpendicular to the c-axis). The agreement is reasonable for the 3D case, and is better for the quasi-2D system, where the finite spatial extent of the 2D electron gas in the symmetric planar layer is taken into account.

For GaAs/Al_xGa_{1-x}As quantum wells and superlattices, the polaron effect is found to decrease the energy of the shallow donor states at low magnetic fields and to lead to a resonant splitting of the energies at high magnetic fields. The results are in very good agreement with available experimental far-infrared optical data in the whole magnetic-field range.

Optical Properties of Quantum Dots: Effects of the Polaron Interaction

In order to interpret the phonon-assisted optical transitions in semiconductor quantum dots, a theory was developed by Fomin, Gladilin, Devreese *et al.* comprising the exciton interaction with both adiabatic and Jahn–Teller phonons, and also the external nonadiabaticity (pseudo-Jahn–Teller effect). The effects of nonadiabaticity of the exciton–phonon system are shown to lead to a significant enhancement of phonon-assisted transition probabilities and to multiphonon optical spectra which are considerably different from the Franck–Condon progression (see Figure 9). The calculated relative intensity of the phonon satellites and its temperature dependence compare well with the experimental data on the photoluminescence of CdSe quantum dots, both colloidal and embedded in glass. These results clearly demonstrate a breakdown of the adiabatic approximation when describing the polaron interaction in quantum dots.

Small Polarons

An electron or a hole trapped by its self-induced atomic (ionic) displacement field in a region of linear dimension, which is of the order of the lattice constant, is called a 'small polaron'. As distinct from large polarons, small polarons appear due to short-range forces.

Experimentally small-polaron effects have been analyzed, e.g., in KCl, LiF, NiO, MnO, TiO_2, $BaTiO_3$, $SrTiO_3$, $LaCoO_3$. More recently, Alexandrov and Mott (1996) surveyed both the principles and the main results of the small-polaron theory in the context of the (bi)polaronic approach to describe the physics of high-T_c superconductors.

Spectroscopic manifestations of both large and small polarons have been found by Eagles *et al.* in the infrared optical absorption spectra of $Pr_2NiO_{4.22}$. The infrared reflectivity spectra on a crystal of this material were measured between 30 and 20 000 cm^{-1}. Mid-infrared conductivity data for frequencies between 1000 and 16 000 cm^{-1} were obtained by Kramers–Kronig transformation of those reflectivity spectra. The resulting optical absorption spectrum was quantitatively interpreted (see Figure 10) using the assumption that in $Pr_2NiO_{4.22}$ two types of polarons, small and large, coexist but do not mix with each other. The contribution due to the transitions between the large-polaron states, which dominates the absorption in the low-frequency region, was calculated using the arbitrary coupling theory by Devreese *et al.* for the coupling constant $\alpha = 3$.

In summary, the polaron concept has been proven to be one of the corner-stones of modern solid-state optics.

Quantum Wells and GaAs-Based Structures

P Blood, Cardiff University, Cardiff, UK

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

A quantum well is a potential minimum within a semiconductor structure which is sufficiently thin to localize charge carriers on a length-scale similar to their de Broglie wavelength which, for an electron in GaAs at room temperature, is about 30 nm. When electrons are localized in this way their electronic and optical properties are determined by quantum mechanical aspects of their behavior which are not apparent in larger-scale structures. The potential well is usually formed by a sandwich of a thin layer of narrow-gap semiconductor between two layers of a wider gap material as depicted in Figure 1. Typical quantum wells have widths of about 5 nm and the key to their routine production has been the development of advanced epitaxial semiconductor crystal growth techniques such as metalorganic vapor phase epitaxy (MOVPE) and molecular beam epitaxy (MBE). The most significant application of these structures has been in opto-electronic devices, especially laser diodes, and in this article I describe how electrons behave in quantum wells with particular reference to optical properties.

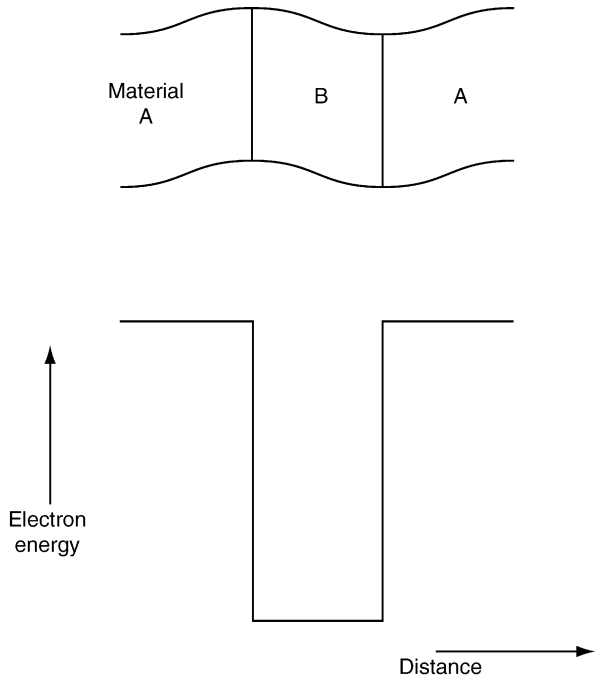

Figure 1 Electron energy diagram illustrating the formation of a potential well by sandwiching a layer of narrow gap semiconductor material (B) between two wider gap layers (A).

The optical properties of semiconductors are usually considered in terms of transitions of electrons between quantum mechanical energy levels, as in the Bohr atom. An alternative description is to consider the spatial displacement of electrons in the oscillating electric field of the electromagnetic radiation. These two descriptions are linked through Schrödinger's equation. For each energy state there is an associated wavefunction which determines the spatial probability distribution of electrons in the state. Consequently, a change in quantum state implies a change in spatial distribution and energy of the electron system. Both approaches are used: here I adopt the viewpoint of transitions between energy states.

We begin with a quantum mechanical description of electrons in a 'bulk' material, as appears in many textbooks. Here electrons are constrained by a three-dimensional potential well of extent given by the sample dimensions, typically millimeters or centimeters and therefore large compared with the de Broglie wavelength. Then we examine what happens when the size of the sample is reduced in one direction: in the limiting case of a quantum well electrons are able to move in only two directions. Quantum confinement is also possible in two or three dimensions to produce a quantum wire or quantum dot, respectively, and it is easy to use the concepts developed in this article to determine the properties of such systems.

Electron States in Bulk Material

We first consider the behavior of an electron in one direction (the x-direction) within a potential well with large dimensions (side length L), then generalize this to three directions (see Figure 2). The wavefunction ψ_n and energy E_n (measured with respect to the bottom of the well) are given by solutions of Schrödinger's equation, which within the well is:

$$\frac{\hbar^2}{2m}\frac{\mathrm{d}^2\psi_n}{\mathrm{d}x^2} = E_n \qquad [1]$$

It is assumed that the potential is infinitely deep compared with the energy of the electrons.

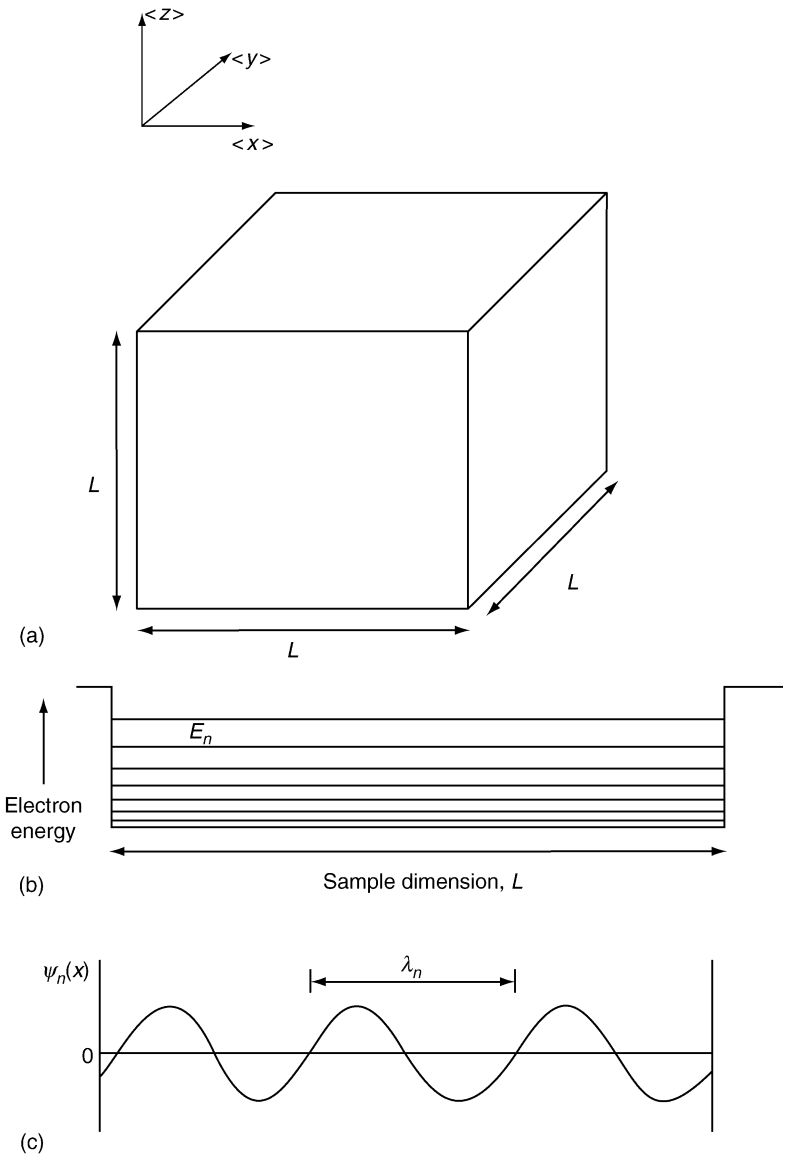

Figure 2 The properties of electrons in a large cubic sample (a) can be obtained by solving Schrödinger's equation for the potential well formed by the sample in each direction (b). This potential well keeps the electrons within the material. The wavefunctions $\psi(x)$ shown in part (c) satisfy cyclic boundary conditions as described in the text, leading to a series of electron energy levels, E_n, given by eqn [3], shown in (b) of the figure.

Within the sample the electrons are described by plane waves of the form $\psi_n = A_n \sin(k_n x)$, where k_n is a wavevector ($= 2\pi/\lambda_n$, where λ_n is the wavelength), and substitution into eqn [1] gives the corresponding energy eigenvalues as

$$E_n = \frac{\hbar^2 k_n^2}{2m} \qquad [2]$$

where m is the mass of the electron. [Substituting $E_n = k_B T$ at room temperature (0.025 eV) and using an effective mass of $0.067m_0$ (for GaAs) in eqn [2] gives $k_n = 2.1 \times 10^8$ m^{-1} and $\lambda = 30$ nm.] Applying cyclic boundary conditions which permit traveling-wave solutions of eqn [1] the wavelength must satisfy the condition $\lambda_n = nL$, i.e., $k_n = 2\pi n/L$, as illustrated in Figure 2, where n is an integer. The dimensions of a typical sample are much greater than the 'size' of an electron so n can be a very large number. The energy eigenvalues are therefore given by

$$E_n = \frac{\hbar^2}{2m}\left(\frac{2\pi n}{L}\right)^2 \qquad [3]$$

This treatment can be extended by solving eqn [1] for motion in three orthogonal directions, x, y, and z. In this case electron motion is described by a wavevector $\mathbf{k}$ comprising components k_x, k_y, k_z, each of which satisfies the cyclic boundary condition in the respective direction. We take the sample to be of dimension L in each direction with no loss of generality. Thus (representing unit vectors by $\langle\mathbf{x}\rangle$, etc.)

$$\begin{aligned}\mathbf{k} &= k_x\langle\mathbf{x}\rangle + k_y\langle\mathbf{y}\rangle + k_z\langle\mathbf{z}\rangle \\ &= \frac{2\pi n_x}{L}\langle\mathbf{x}\rangle + \frac{2\pi n_y}{L}\langle\mathbf{y}\rangle + \frac{2\pi n_z}{L}\langle\mathbf{z}\rangle \end{aligned} \quad [4]$$

the energy is

$$E = \frac{\hbar^2}{2m}\left\{k_x^2 + k_y^2 + k_z^2\right\} \quad [5]$$

and the wavefunction takes the vector form

$$\psi_k(\mathbf{r}) = A_k \sin(\mathbf{k}\cdot\mathbf{r}) \quad [6]$$

$\psi_n^2(\mathbf{r})$ represents the probability of an electron being at the location $\mathbf{r}$. Each allowed electron state obtained by solution of Schrödinger's equation is specified by a unique combination of the numbers $(n_x\, n_y\, n_z)$, which take both positive and negative values corresponding to plane waves traveling in positive and negative directions. The Pauli exclusion principle states that only one electron of each spin can occupy a given quantum state so the amplitude of each wavefunction is normalized such that

$$\int \psi_k^2(\mathbf{r})\, \mathrm{d}\mathbf{r} = \int [A_k \sin(\mathbf{k}\cdot\mathbf{r})]^2\, \mathrm{d}\mathbf{r} = 1 \quad [7]$$

where the integrals are evaluated over the volume of the sample. Since the amplitude of these solutions is constant throughout the sample electrons may be anywhere in the sample with equal probability. The motion of an *individual* electron of momentum $\hbar\mathbf{k}$ is represented by a wavepacket formed by combination of a number of wavefunctions having similar values of $\mathbf{k}$.

Because the sample dimensions are large the energies of the states allowed by Schrödinger's equation take a series of very closely spaced values for increasing integer values of n as shown in Figure 2b. Substituting a typical sample size of $L = 1$ mm into eqn [3], the $n = 1$ and 2 states are separated by only 7×10^{-11} eV in GaAs and these values are very small compared with thermal energies: at room temperature, $k_B T = 0.025$ eV. The allowed values of $\mathbf{k}$ and E are discrete and there is a finite but very large number of allowed states in the sample. Since these are very closely spaced we can regard $\mathbf{k}$ and E as continuous variables and the allowed energy states form a continuum. We can calculate the number of allowed energy states $\mathrm{d}N$ in a small energy interval, $\mathrm{d}E$, and hence determine the density of states in energy $g = (\mathrm{d}N/\mathrm{d}E)$ (the number per unit energy interval) at any value of energy.

Electron States in Quantum Wells

Now imagine a sample where the length of one side is reduced in the z-direction (L_z), as illustrated in Figure 3. Gradually the allowed values of k_z become more widely spaced as a consequence of the boundary conditions (eqn [4]). Eventually the width of the potential well becomes similar to the wavelength of the plane-wave state corresponding to the lowest energy level in the well. In these circumstances electron motion is not possible in the z-direction and the wavefunctions become standing waves with boundary conditions $n(\lambda_n/2) = L_z$ in an infinitely deep potential (where n_z takes only positive values) and the amplitude of the wavefunction outside the well must be zero. The lowest energy state, given by eqn [5] with $n_x = n_y = n_z = 1$, no longer lies near the bottom of the potential well. Since the energies associated with motion in the x and y directions remain very small (of order 10^{-10} eV derived earlier) because L_x and L_y are large, the energy of the lowest state is effectively determined by the z-dimension because it is very small, so eqn [5] gives

$$E_{n_z} = \frac{\hbar^2}{2m}\left(\frac{n_z\pi}{L_z}\right)^2 \quad [8]$$

for the lowest energy state in the well. For $L_z = 5$ nm (and $m = 0.067$) E_1 is 0.22 eV above the bottom of the well. Equation [8] shows that this energy can be changed by choice of the well thickness. A simple interpretation of this behavior is as follows. When L_z becomes very small it is no longer possible for the z-component of the wavefunction of the lowest energy state to satisfy the boundary condition of zero amplitude at opposite sides of the sample. The condition can only be satisfied by wavefunctions which have a smaller wavelength, and consequently a higher energy.

Electrons can occupy states defined by all values of $(n_x\, n_y\, n_z)$, thus for $n_z = 1$ there is a continuum of allowed states at increasing energies corresponding to increasing values of $(n_x\, n_y)$ and corresponding to motion in the (x, y) plane (Figure 4a). Since L_x and L_y are both large these states are closely spaced and form a continuum. There is a similar continuum of energy

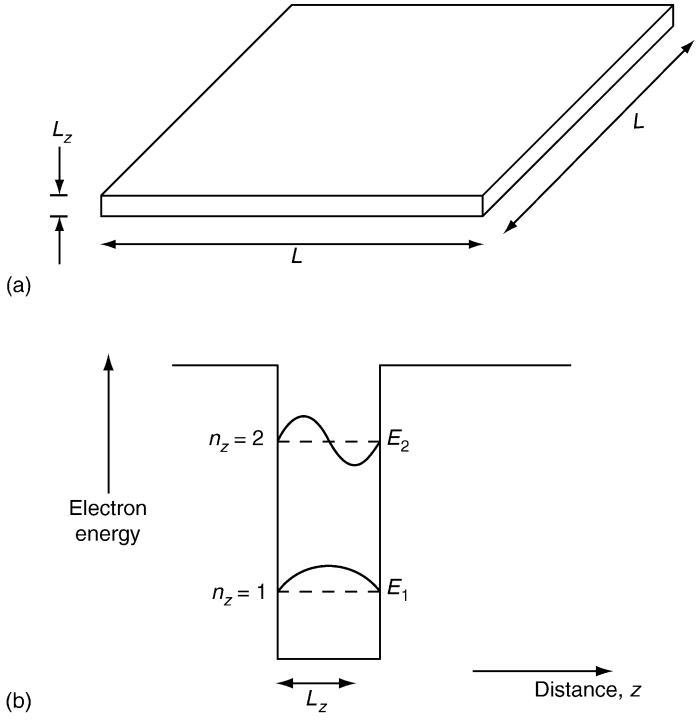

Figure 3 Electron energy diagram (b) for a sample (a) in which one dimension, L_z, is very small. The electron motion in the z-direction is constrained and the associated energy levels become widely spaced, defined by the integers $n_z = 1, 2, \ldots$ in eqn [8]. The wavefunctions in the z-direction, $\psi(z)$, are also illustrated for the first two electron levels.

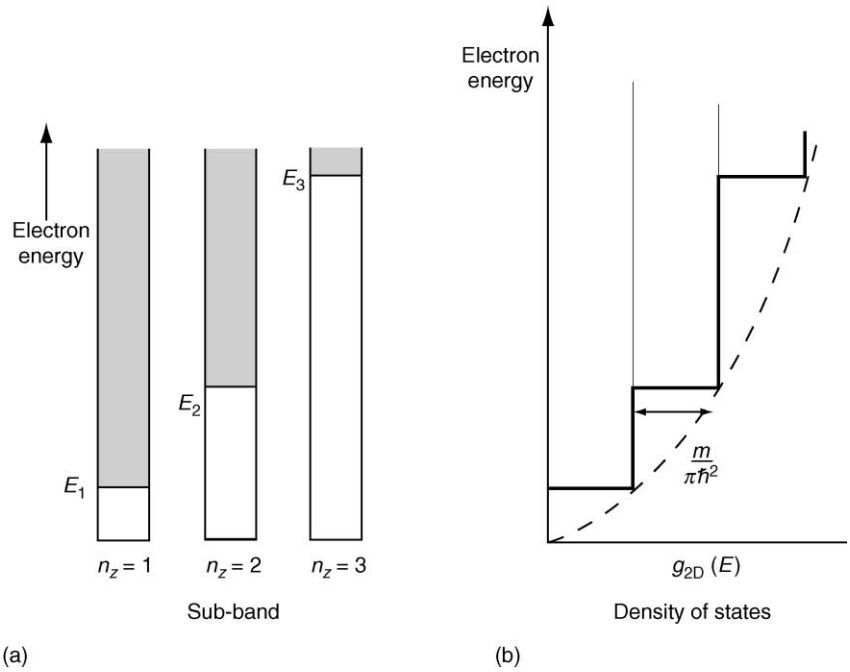

Figure 4 (a) Electron energy diagram showing the energy states associated with unconstrained motion in the (x, y) plane for each sub-band formed by localizing the electrons in the z-direction, defined by $n_z = 1, 2, 3$, etc. When all these allowed states are summed at any energy and expressed as a number of states per unit energy interval we obtain the density of states function $g_{2D}(E)$ shown in (b). This has a series of steps corresponding to each sub-band edge.

states above the energy levels for $n_z = 2, 3$, etc. Thus the energy level diagram is a series of sub-bands, each defined by n_z and with a continuum of states associated with motion in two dimensions in the (x, y) plane, as shown in Figure 4. The number of continuum energy states in a given sub-band in a small energy interval gives the density of states for both spin directions

$$g_{2D}(E) = \frac{m}{\pi\hbar^2} \qquad [9]$$

per unit energy interval per unit sample area.

The density of states is independent of n_z and therefore the same for all sub-bands, and is independent of energy. The density of states function is therefore a series of steps of height given by eqn [9] at each sub-band energy as illustrated in Figure 4b. The density of states per unit area within a given sub-band is independent of L_z as a consequence of dealing with a two-dimensional system.

In real samples the quantum well is not infinitely deep: typically the well depth is in the range 100–400 meV, consequently electrons are not totally confined to the well but are able to penetrate into the barrier material by quantum mechanical tunneling. Solution of Schrödinger's equation for a finite well (treated in many quantum mechanics textbooks) again yields a series of sub-bands, finite in number and with an energy spacing smaller than that given by eqn [8]. In a typical GaAs well the lowest energy state may be about 100 meV from the bottom of the well. The density of states in each sub-band, which is due to the (x, y) motion, remains unchanged. The wavefunction in the z-direction $F(z)$ comprises a sine wave-like standing wave within the well and an exponentially decaying wave in the barrier representing tunneling (Figure 5). The wavefunction is therefore made up of (x, y) plane-wave components and the localized z component and is of the form

$$\Psi_k(\mathbf{r}) = A_k \sin(\mathbf{k}_{xy} \cdot \mathbf{r}_{xy}) F(z) \qquad [10]$$

where $\mathbf{k}_{xy}$ and $\mathbf{r}_{xy}$ are the wavevector and position vector in the (x, y) plane. This wavefunction is again normalized according to eqn [7] such that each state is occupied by one electron of a given spin direction. We see from Figure 5 that we cannot regard the electron as being localized in the well: the electron distribution in the z-direction is specified by the probability distribution $F^2(z)$.

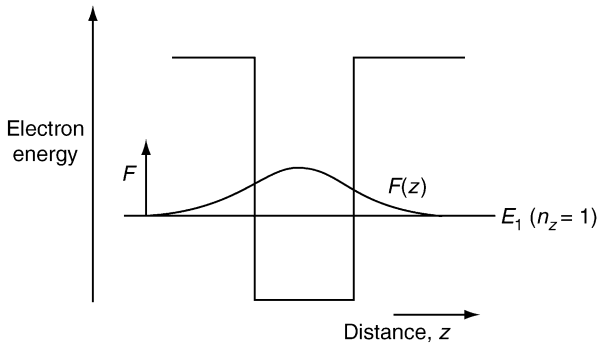

Figure 5 Illustration of the envelope wavefunction $F(z)$ in the z-direction for an electron localized in the $n_z = 1$ sub-band of a well of finite depth. The electron is able to penetrate the barrier by tunneling and this is represented by the decaying part of the wavefunction outside the well.

Occupancy of States in Quantum Wells

The density of states function describes the energy distribution of allowed states in the quantum well. Whether or not particular states are occupied by electrons is determined by the electron concentration and the temperature through the thermodynamic properties of the system. In most cases electron–electron scattering is sufficiently rapid to bring the electron population into an internal equilibrium. Furthermore the interaction between the electrons and the crystal lattice is able to redistribute energy between the two systems so that the lattice and the electron distribution have the same temperature. The electron distribution can therefore be described by Fermi–Dirac statistics for which the probability of a state at energy E being occupied with an electron is

$$f(E) = \frac{1}{1 + \exp\left\{\dfrac{E - E_f}{k_B T}\right\}} \qquad [11]$$

where E_f is the chemical potential (which can be equated with the Fermi level for electrons), T is the lattice temperature and all energies are positive quantities measured with respect to the same arbitrary zero. The energy distribution of electrons in the well, $n(E)$, is then the product of the density of states function, $g_{2D}(E)$, and the occupation probability, $f(E)$, as depicted in Figure 6. The total number of electrons, n, is the integral over energy. Combining eqns [9] and [11], for a single sub-band gives:

$$n_a = \frac{mk_B T}{\pi\hbar^2} \ell n\left\{1 + \exp\left(-\frac{E_n - E_f}{k_B T}\right)\right\} \qquad [12]$$

per unit area, single sub-band.

We cannot specify the carrier density in the well 'per unit volume' since the extent of the distribution in the z-direction is not defined because electrons

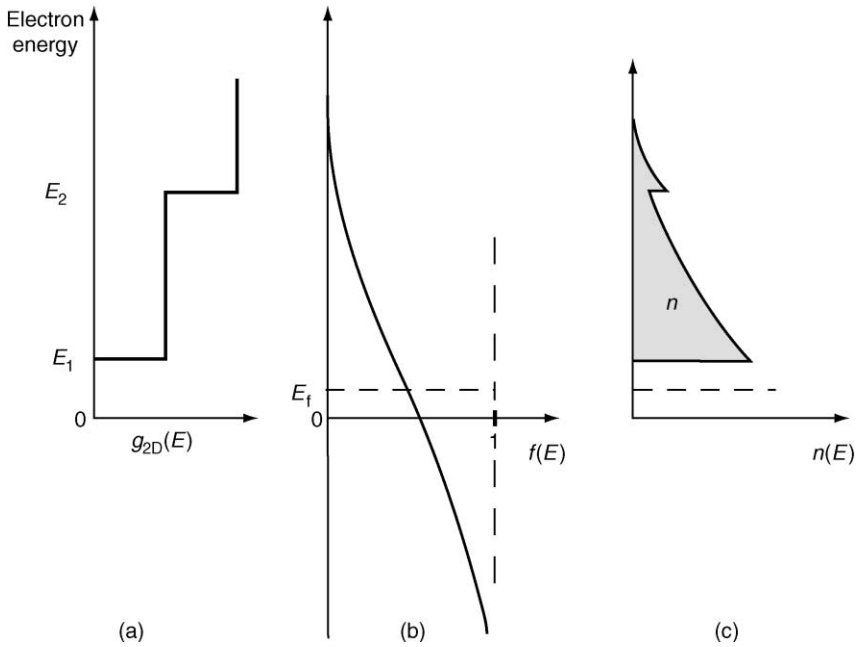

Figure 6 (a) The density of states function for a quantum well, with the value of $g_{2D}(E)$ on the horizontal axis indicating how the density of states varies with increasing electron energy. (b) is an illustration of the probability that a state is occupied by an electron, showing how $f(E)$ varies with increasing electron energy, given by eqn [11]. The actual density of electrons in a given energy interval at any energy $n(E)$ is given by the product of the density of available states and the probability that the state is occupied as shown in (c). The integral of $n(E)$ over energy gives the total density of electrons given for each sub-band by eqn [12].

may tunnel into the barrier material. The electron distribution is properly specified as a number per unit area having a probability distribution in the z-direction given by the function $F(z)$. Where more than one sub-band is populated the total electron density is obtained by adding the contributions from each sub-band each given by eqn [12] with the same Fermi energy and the appropriate sub-band energy. We always use Fermi factors to specify the probability of occupation of a state by an *electron*. The probability that a state is empty is $(1 - f)$.

Formation of Quantum Wells

A quantum well is formed by sandwiching a narrow gap semiconductor layer (E_{g1}) between two layers of wider gap material (E_{g2}). To avoid the formation of defects and dislocations, which have a deleterious effect on many properties of the structure, the constituent materials must have the same lattice parameter. Figure 7a is an energy band diagram for an n-type double heterostructure with layers of micron dimensions. At each interface there are discontinuities in the conduction and valence bands, ΔE_c and ΔE_v, respectively, which account for the difference in the band gaps of the two materials, ΔE_g. While the value of ΔE_g is known for any system, the manner in which this difference is apportioned between the two band edges is not known a priori and the values of ΔE_c and ΔE_v must be obtained from experiment. The discontinuities are often expressed as fractions Q_c, Q_v of the band gap difference:

$$\Delta E_c = Q_c \Delta E_g, \qquad \Delta E_v = Q_v \Delta E_g \qquad [13]$$

In equilibrium the Fermi energy is constant across the diagram and there is a band-bending region on each side of the discontinuity such that the conduction band edges return to their equilibrium energy values at large distances from the interface. The extent of these regions is determined by the discontinuity and the doping level and is typically 200–1000 nm. At each single interface a triangular well is formed which localizes electrons and whose precise shape is determined by the doping density, the carrier distribution and discontinuity through simultaneous solution of Schrödinger's equation and Poisson's equation. Single heterointerfaces only localize the majority carrier. Quantum confinement of both types of carrier can be achieved by a very thin narrow gap semiconductor layer.

When the layer of narrow gap material is made thinner than the band-bending regions, the

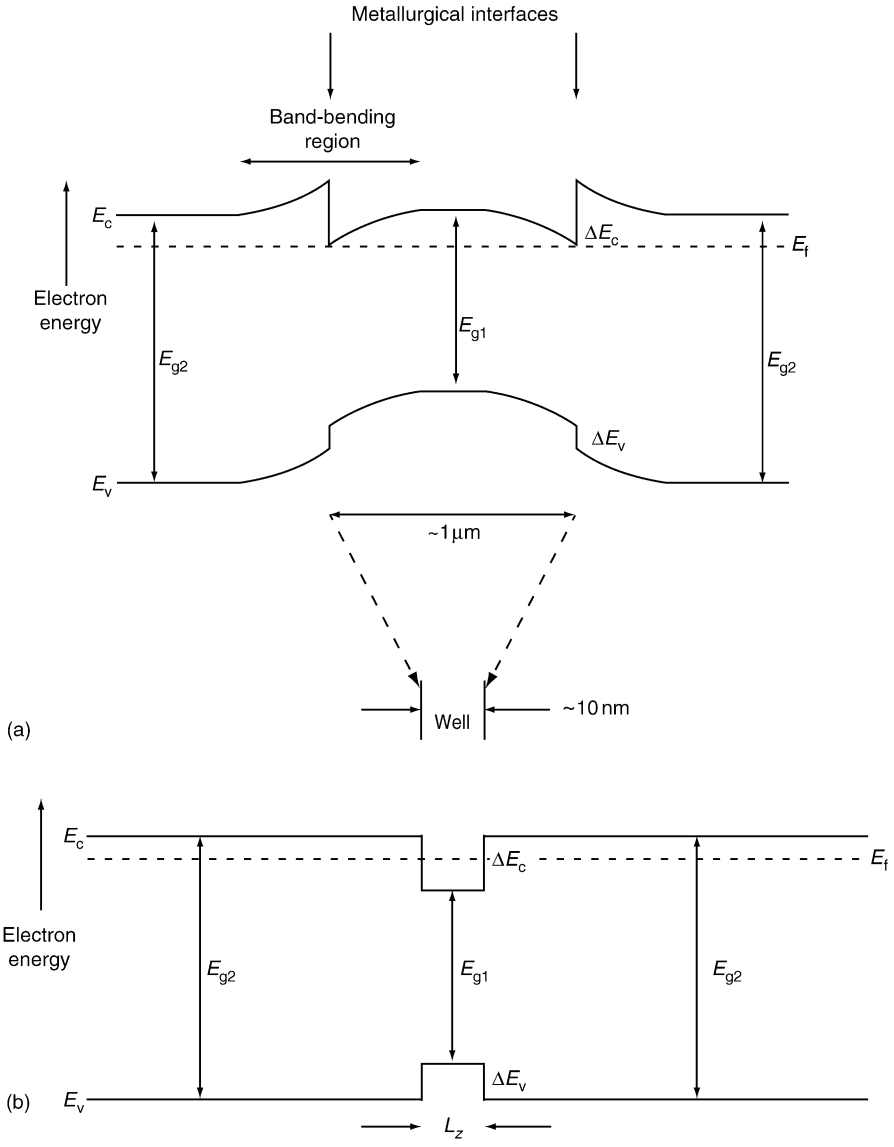

Figure 7 Electron energy diagrams showing the formation of a quantum well as a very thin double heterostructure made up of materials of band gaps E_{g1} and E_{g2}. When the layers are thick the energy diagram is influenced by band bending at the interfaces as shown in (a). When the narrow gap layer is made thinner than the band-bending distances a rectangular well is formed in the conduction and valence bands with depths determined by the respective band offset as shown in (b). On the small distance scale of the well the bands are flat in each region of the structure.

conduction band edge in this layer is not able to regain its bulk equilibrium position and the two triangular wells coalesce as illustrated in Figure 7b. When the well is sufficiently thin, say L_z less than 20 nm, the band-bending across this layer is negligibly small and the well becomes effectively rectangular. This well accumulates electrons from the surrounding barrier material and its potential relative to the Fermi level rises such that there is band bending in the barrier material on each side of the well inhibiting further accumulation. Since the band bending in the barrier occurs on a distance of hundreds of nanometers (being determined by the doping density) it is not apparent over the distance scale of the diagram of the quantum well, which is on the order of 10 nm. Consequently, as shown in Figure 7b, the well can be drawn as a rectangle to a good degree of approximation. This thin, narrow gap layer localizes both electrons and holes. The form of the well is determined by the respective band discontinuities, ΔE_c and ΔE_v, and the thickness of the layer.

Potential wells formed in this way are the basis for most quantum-confined device structures.

Other forms are possible. In certain material combinations ΔE_c or ΔE_v may be negative, meaning that, at the interface, both discontinuities are in the same sense and only one carrier type is confined in the thin narrow gap material. These are known as 'type II' structures. If there is an electric field across the well due to doping or strain (piezoelectric) effects the well becomes triangular. Wells can also be engineered with steps in the potential profile and multiple well systems can be grown in which the states are quantum mechanically coupled. All these variants provide opportunities to engineer the properties of the structure.

One important development of the rectangular quantum well deserves mention. It is possible for the well material to have a different lattice parameter to that of the surrounding barrier material provided that the strain energy can be accommodated elastically within the structure. This means that the strain energy in the layer must be below the energy necessary for formation of dislocations and this translates into an upper limit on the layer thickness (the critical thickness) for a given mismatch. Incorporation of elastic strain is significant because relaxing the lattice match requirement widens the choice of well and barrier materials and because strain modifies the properties of the electronic states in the quantum well and these effects can be used to advantage in the design of devices.

Here we concentrate on the rectangular potential well. Such wells are widely used, particularly in opto-electronic devices, and this structure provides the basic concepts which lie at the heart of all quantum-confined systems. We consider the 'model' lattice-matched quantum well system: a GaAs well bounded by AlGaAs barriers.

GaAs/AlGaAs Quantum Well Structures

As Al is substituted for Ga in the $Al_xGa_{1-x}As$ alloy system the direct band gap increases from 1.424 eV in GaAs ($x = 0$) to 3.018 eV in AlAs ($x = 1$) (Figure 8) while the lattice parameter remains unchanged. A quantum well is formed using a narrow GaAs layer sandwiched between barrier layers of $Al_xGa_{1-x}As$ having a composition chosen to give the desired well depth. The whole structure is grown on a GaAs substrate. The band discontinuity ratio between GaAs and $Al_xGa_{1-x}As$ is independent of alloy composition (ΔE_c and ΔE_v are constant fractions of ΔE_g as x is varied) with $Q_c = 0.66$ and $Q_v = 0.33$. For a typical barrier composition of $x = 0.3$,$\Delta E_g = 0.374$ eV and ΔE_c and ΔE_v are 0.247 eV and 0.127 eV, respectively.

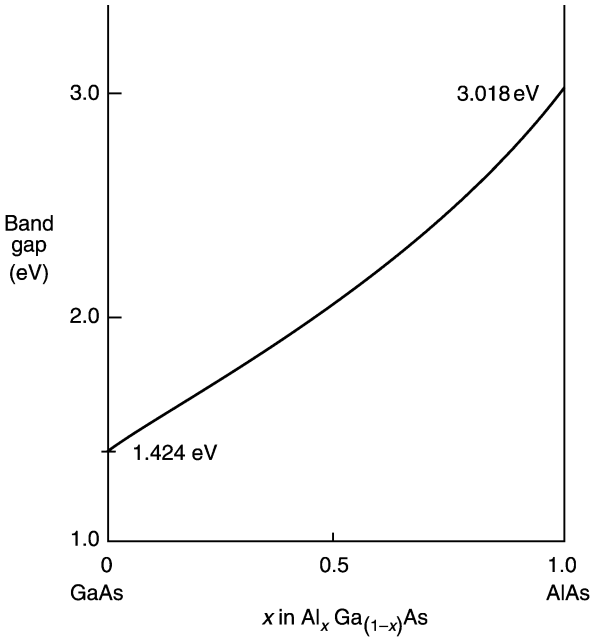

Figure 8 Variation of the direct band gap of $Al_xGa_{(1-x)}As$ with Al content (x).

Optical Properties of AlGaAs/GaAs Quantum Wells

General Principles

Figure 9 illustrates a transition of an electron between an occupied state at E_1 in the $n_z = 1$ sub-band in the conduction band and an empty state (i.e., a hole) at E_2 in the $n_z = 1$ sub-band in the valence band, resulting in emission of a photon of energy $h\nu = E_1 - E_2$ as required by energy conservation. This is the process of luminescence (or spontaneous emission), which requires external excitation such as illumination (photoluminescence) or biasing a p-n junction (electroluminescence, as in a light-emitting diode). Alternatively, incident light may promote an electron from an occupied state in the valence band to an empty state in the conduction band with the consumption of the energy of a photon. This is the process of optical absorption.

At typical temperatures the electrons and holes are at energies near to their respective band edges so the photon energy $h\nu$ is close to the separation of the $n_z = 1$ sub-bands. Since these energies are determined by the well width it is possible to change the photon energy for emission or absorption by changing the well width. As the well width is reduced the energy separation increases and the wavelength of light emitted by the structure is reduced. This ability to engineer the emission wavelength by simply adjusting

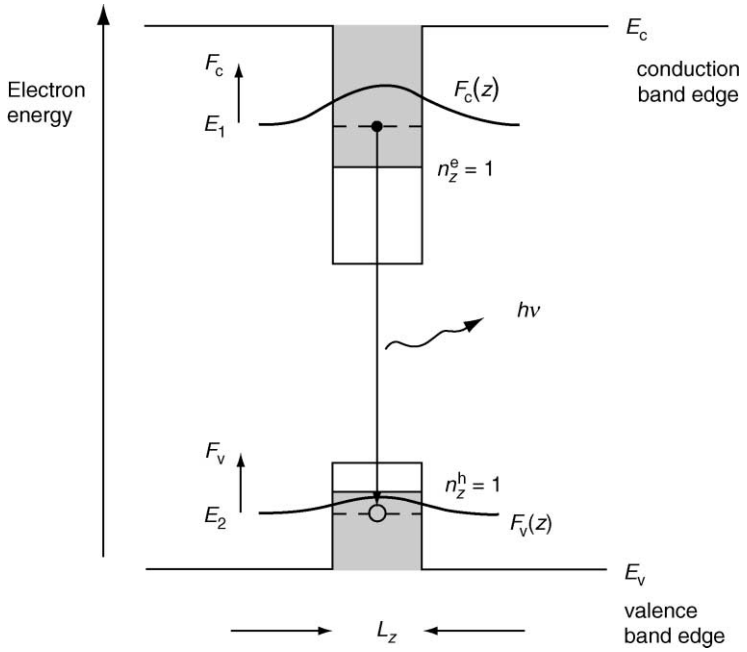

Figure 9 Illustration of a downward optical transition of an electron from a state in the $n_z = 1$ conduction sub-band to an empty state (hole) in the $n_z = 1$ valence sub-band resulting in emission of a photon of energy $h\nu = E_1 - E_2$. The spatial probability distribution of the electron and hole is specified by their respective envelope functions $F_c(z)$ and $F_v(z)$ and the probability of the transition occurring is proportional to their overlap integral, eqn [14].

the well width, without changing the chemical composition of the constituent materials, is one of the major attractions of quantum-confined structures. The shortest wavelength possible for a given material combination is determined by the band gap of the wide gap barrier material alongside the well.

The strength of the luminescence signal or the absorption is determined by the rates at which the electronic transitions occur. In general these rates are determined by the following intrinsic factors.

1. *The quantum mechanical probability of an electron making a transition between a full and an empty state*. This depends upon the 'matrix element' for the transition, which is a fundamental property of the well material and the overlap of the envelope functions. The electron and hole in the initial and final states must be in the same region of space and if the spatial distributions of electrons and holes, determined by F_c and F_v, do not overlap the probability for an electron to make a transition to the hole state is very low. The overlap is almost complete in a rectangular well (see Figure 9), but is only partial in a triangular well. The transition probability is proportional to

$$I_{\text{overlap}} = \left\{ \int F_v(z) F_c(z)\, dz \right\}^2 \qquad [14]$$

2. *The probability of occupation of initial and final states by electrons, specified by the Fermi factors* (eqn [11]). The initial state must be occupied and the Pauli exclusion principle prohibits an electron entering a final state which is already occupied. Thus for a downward transition resulting in emission of light the rate is proportional to $f_c(1 - f_v)$.
3. *The density of initial and final states* (eqn [9]). The more states there are within a given small energy interval, the greater the emission rate per unit energy.
4. *Photon distribution*. For processes such as optical absorption, which are 'induced' by the presence of a photon, the transition rate is also proportional to the photon density in the region of the well. Because the electrons are not wholly localized in the well, and because the spatial extent of the optical field is larger than that of the carriers, the coupling between the photon field (intensity $I_{\text{ph}}(z)$) and the carrier probability distributions is expressed as

$$I_{\text{coupling}} = \frac{\left\{ \int F_v(z) [I_{\text{ph}}(z)]^{1/2} F_c(z)\, dz \right\}^2}{\int I(z)\, dz} \qquad [15]$$

5. *Optical mode density*. The emission rate also depends upon the density of optical modes

available to receive the recombination radiation. In most situations the emission occurs into the cavity of free space which is very large compared with the wavelength of the radiation so the modes are very closely spaced and the cavity can accept radiation at any transition energy (this is the well-known Raleigh–Jeans theory of cavity radiation). However, in some special situations the cavity has dimensions comparable with the wavelength of the radiation (microcavities) and then the modes are widely spaced. In such a microcavity, the optical cavity effectively controls the electronic transitions.

Optical Absorption

Figure 10 is an optical absorption spectrum for a GaAs quantum well measured with light incident normal to the plane of the quantum wells. A series of steps can be seen which correspond to absorption at increasing photon energy between increasing orders of sub-bands, $E_{1e} \rightarrow E_{1h}$, $E_{2e} \rightarrow E_{2h}$, etc. Normally $n_z = 1$ to $n_z = 2$ transitions are forbidden in rectangular wells. At each step there is a pair of peaks (not always resolved) and above each step the absorption is roughly constant, following the step-like density of states function sketched in Figure 4. The peaks are due to the formation of excitons which are weakly bound electron–hole pairs. In bulk materials excitons are only observed at low temperatures whereas in quantum wells the localization increases the binding energy (E_{bX}, typically 6–8 meV) such that they are observed at room temperature. The excitonic peak is at an energy E_{bX} below the sub-band separation. There are in fact two different kinds of electrons in the valence band with different masses so there are pairs of $n_z = 1, 2, 3, \ldots$ sub-bands due to the different confinement energies for the different valence electrons. Spectra of this kind provided the first evidence for the distinctive sub-band structure of quantum well systems produced by carrier confinement. Absorption measurements provide data on the energy spacing of the sub-bands in the well, and it is possible to determine the well width and depths, from which the band offsets can also be determined.

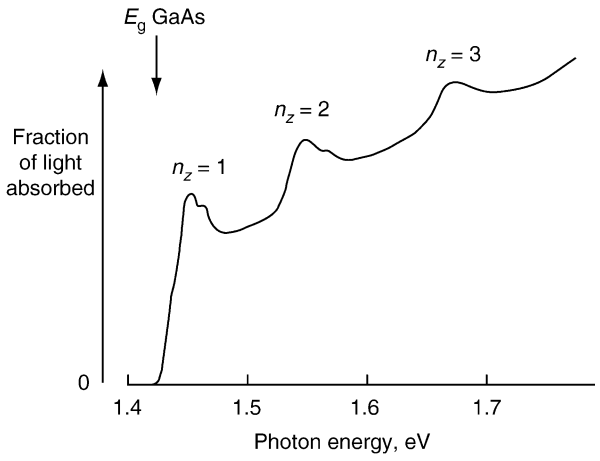

Figure 10 Absorption spectrum of a multiple quantum well structure having 10 nm GaAs wells measured at room temperature. The absorption edges corresponding to transitions between $n_z = 1, 2$, and 3 pairs of sub-bands can be identified. The peaks are due to absorption by formation of excitons.

The strength of the absorption is also of interest because it provides a measure of the optical matrix element if the Fermi factors f_c and f_v are known. If the incident optical beam is very weak such that the absorption process excites very few electrons then the system remains close to thermal equilibrium so the upper states are empty ($f_c = 0$) and the lower states are full ($f_v = 1$).

In *bulk material* the change in photon flux over a small distance Δx is proportional to the flux Φ and the distance traveled

$$\Delta\Phi = -\Phi\alpha\Delta x \qquad [16]$$

where α is the absorption coefficient which has units L^{-1}. This results in an exponential decrease of photon flux with distance traveled through the material

$$\Phi(x) = \Phi_0 \exp(-\alpha x) \qquad [17]$$

For a quantum well structure with light incident in the z-direction perpendicular to the plane of the quantum well, the fraction of light absorbed by a single well by transitions between a single sub-band pair (e.g., transitions between the $n_z = 1$ conduction and valence sub-bands) is independent of the thickness of the well because the density of states for a single sub-band is independent of well thickness. The strength of the absorption cannot be expressed by an absorption coefficient but by the fraction of light absorbed per well:

$$\Delta\Phi = -\gamma_w\Phi \qquad [18]$$

This arises because the quantum well is effectively a sheet in the z-direction: changing its thickness does not change the density of states per unit area (eqn [9]) and we cannot specify the electron concentration along the z-direction. This behavior also occurs because the well is much thinner than the wavelength of the light and it is not possible to

specify the variation of photon flux on a distance scale smaller than the wavelength. The barrier material surrounding the well has a wider band gap and does not absorb at the photon energies absorbed by the well. The well thickness does affect the sub-band spacing and at a fixed photon energy the absorption increases as the well width is decreased as light is absorbed by transitions between more sub-bands. Equation [18] applies individually to each sub-band because the density of states is the same for each sub-band.

In a multiple well system, the fraction of light transmitted through N independent wells is

$$T_N = \{1 - \gamma_w\}^N \qquad [19]$$

so the fraction of light absorbed by such a system is

$$\frac{\Delta\Phi}{\Phi} = -\left[1 - \{1 - \gamma_w\}^N\right] = -N\gamma_w \qquad [20]$$

which is proportional to the number of wells when $\gamma_w \ll 1$.

The fraction of light absorbed by transitions between a single pair of sub-bands for a rectangular GaAs quantum well is predicted to be about 0.01, and a similar value has been obtained from absorption measurements. In a rectangular well the envelope function overlap is complete; however, in a triangular well of the same material the absorption is reduced by the smaller overlap of the envelope functions.

Photoluminescence and Spontaneous Emission

We turn now to discuss the optical emission from quantum wells as a result of external excitation. An external light source with photon energy above the effective band gap produces excess electron–hole pairs by excitation of electrons from the valence band. These rapidly lose their excess energy and thermalize to the sub-band edges to take up Fermi energy distributions. The electrons subsequently recombine to vacant valence band states by spontaneous emission. The low energy edge of this spectrum corresponds to the sub-band separation and the shape of the spectrum at higher energies corresponds to the thermal distribution of carriers in the bands. At very low excitation intensities where the excess electron population is small the luminescence may be due to recombination of electrons within an exciton and occur at an energy E_{bX} below the sub-band separation. Generally the sub-band separation is several k_BT so only the lowest sub-band is populated and photoluminescence is not seen from higher sub-bands. In this respect absorption measurements provide a more complete characterization of the structure.

While the energy position of features in the photoluminescence spectrum provides useful information, it is difficult to use the strength of the photoluminescence signal to provide quantitative information about the rate of optical transitions within the material because the excitation power and volume within the sample must be known and a known fraction of emitted light must be collected and measured with a calibrated detector. The relative intensity of photoluminescence under standard conditions does provide comparative information and the linewidth of the spectrum at low intensity provides a qualitative indication of 'quality' (e.g., well width variations in the structure). A quantitative determination of the internal recombination rate can be obtained by measuring the decay of the luminescence signal following short-pulse excitation. Fuller discussion can be found in books dealing with the characterization of semiconductor structures.

Concluding Remarks

We have shown that an understanding of the electronic structure of quantum wells follows naturally from quantum mechanical treatments of electrons in bulk materials. When one of the dimensions of the structure is reduced to be similar to the de Broglie wavelength, quantization of the electron motion in this direction becomes apparent. The sub-bands which are formed have a profound effect on the electronic and optical properties when their spacing exceeds thermal energies such that only one band is significantly populated with carriers. The density of states function is a series of steps, each corresponding to a sub-band, and this produces characteristic step features in the optical absorption spectrum. The effective band gap of the structure is controlled by the width of the well. Quantum confinement also increases the binding energy of excitons compared with bulk materials and under low excitation conditions absorption and luminescence spectra are dominated by excitonic features even at room temperature.

One of the most successful application areas of quantum well structures has been in laser diodes. Figure 11 shows experimental data for laser emission wavelengths as a function of well width, showing the dramatic reduction which can be achieved simply by changing the width of the quantum well. Furthermore the step density of

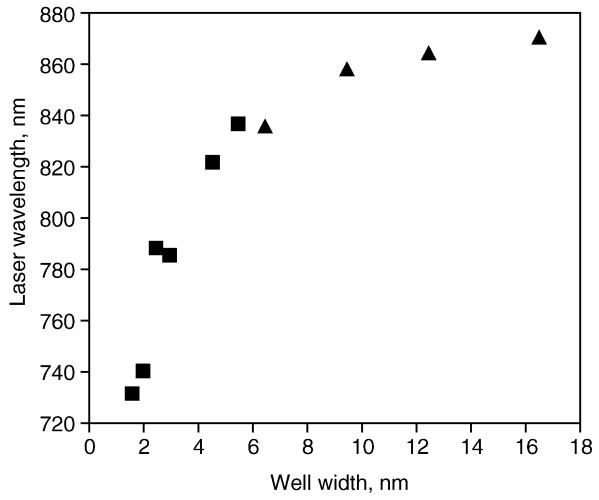

Figure 11 Measured values of the emission wavelength of GaAs/AlGaAs quantum well lasers as a function of well width, showing how the wavelength can be engineered by choice of the well width. states function, characteristic of quantum wells, is one of the fundamental reasons for the reduction in threshold current of quantum well lasers relative to bulk GaAs devices.

We have considered GaAs because it is a model material system for production of quantum well structures. The concepts developed in this chapter are, however, quite general and can be applied to other material systems, other forms of quantum well and quantum wires and dots.

List of Units and Nomenclature

E	energy
E_f	Fermi energy
E_g	bandgap
F	envelope wavefunction
$f(E)$	Fermi–Dirac distribution function
g_{2D}	two-dimensional density of states $[\text{energy}]^{-1}\,[\text{area}]^{-1}$
$\hbar$	Planck's constant divided by 2π
I_{ph}	optical field intensity
$\mathbf{k}$	wavevector
k_B	Boltzmann's constant
m	electron mass
n	carrier density, expressed per unit area in quantum well structures
Q_c, Q_v	heterostructure band offset ratios
$\mathbf{r}$	position vector
t	time
T_N	fraction of light transmitted at normal incidence through N quantum wells
$\langle \mathbf{x} \rangle$	unit vector along x-direction, similarly for y, z directions
α	optical absorption coefficient in a bulk material, per unit length
γ	fraction of light absorbed by a quantum well at normal incidence to the plane of the well
λ	wavelength
Φ	photon flux (photons per unit time crossing unit area)
Ψ	electronic wavefunction
ν	light frequency

Recombination Processes

P T Landsberg, The University of Southampton, Southampton, UK

Introduction

In studies of recombination there occur considerable complications; many are associated with interactions between electrons, electrons and phonons, excitons, bi-excitons, impurity centers, etc. Most of these are not required in the present exposition. Modern work normally assumes that the basics of recombination physics are understood and the present exposition offers an appropriate outline.

Basic Assumptions

Electron–Electron Interactions for Electrons in Bands

The recombination problem in semiconductors is greatly complicated by the interaction of the electrons with each other. This allows one to speak only of the quantum states of the semiconductor crystal as a whole. However, as in metals, so also in semiconductors, a simplified picture is successful. In this, the electron interactions, and other interactions, are first neglected, but are later taken into account as a perturbation. Thus, the electrons are first treated as if they can move through each other; the fact that they collide and deflect each other by virtue of their Coulomb interaction is treated as a perturbation. The transitions are still described within the framework of the single-particle states of the unperturbed problem.

The Effect of Electron–Boson Interactions

Our first approximation is to neglect most (but not all) electron interactions. Later we take into account the two-electron transitions that arise. This two-particle recombination process is referred to as Auger recombination and its inverse as the generation of current carriers by impact ionization. In addition, electrons interact with the radiation and lattice fields and emit or absorb photons or phonons. These electron–boson interactions result in transitions of single electrons in an energy band scheme. We shall attach a superfix 'S' (for single-electron) to the recombination coefficients for such processes. These are then denoted by B^{S} or T^{S} depending whether only bands are involved or whether traps are also involved. They are illustrated in Figure 1, where the solid horizontal lines represent the conduction and valence band edges and the dashed line refers to traps. Note that the two-electron transitions do not have the superfix 'S', while n and p refer to the electron and hole concentrations; N_0 and N_1 are the concentration of unoccupied and occupied trap states, respectively.

Electron–Electron Interaction in Traps

Electron–electron interactions can at least formally be taken into account in connection with electrons trapped in a center: the spectrum is a function of the number, $r\,(=1,2,3,\ldots,M)$, of electrons captured. The 'irremovable' electrons can be included with the ion core. Given that the center captured r electrons (say), it can still be in a variety of quantum states, and they will be denoted by the symbol ℓ, yielding a set of quantum states (ℓ, r) for a center. The energy of such a state, divided by kT to make it dimensionless, is denoted by $\eta(\ell, r)$, yielding the canonical partition function

$$Z_r = \sum_{\ell} \exp[-\eta(\ell, r)] \qquad [1]$$

The location of a center in space will here be considered to be of no significance.

Centers can capture several electrons. This brings in a need for the chemical potentials (or Fermi levels) for r-electron centers. They are here denoted by γ (when divided by kT) and the suffix 'eq' denotes an equilibrium value. Thus, the equilibrium probability of finding an r-electron center in state ℓ is given by:

$$P(\ell, r)_{\mathrm{eq}} = \frac{\exp[r\gamma_{\mathrm{eq}} - \eta(\ell, r)]}{\sum_{s=0}^{M} (\exp s\gamma_{\mathrm{eq}}) Z_S} \qquad [2]$$

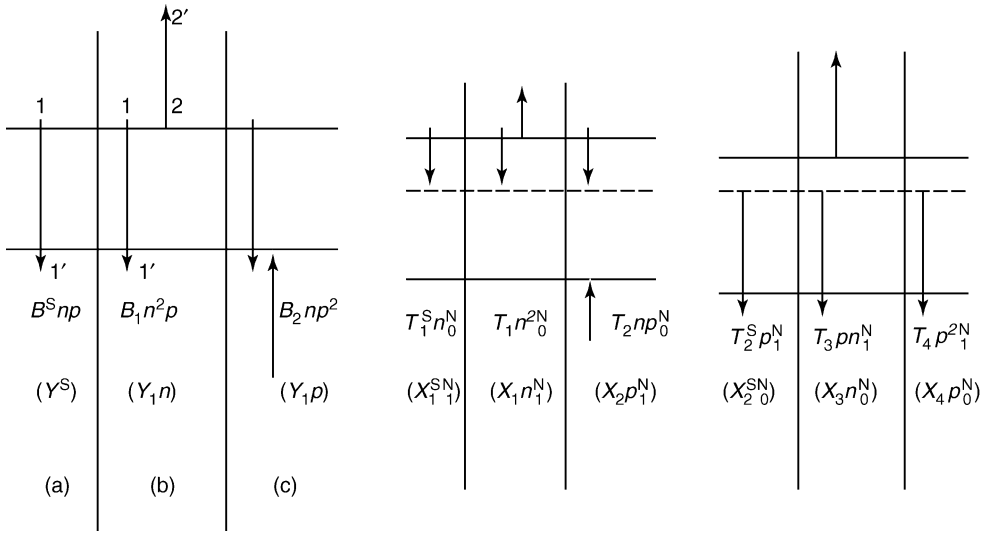

Figure 1 Definition of recombination coefficients. Transition rates per unit volume are stated with each process, and, in brackets, for the reverse process. Thus B_1, B_2, T_1-T_4 refer to Auger processes; B^s, T_1^s, T_2^s refer to single-electron recombination; Y^s, X_1^s, X_2^s refer to carrier generation processes; Y_1, Y_2, X_1-X_4 refer to impact ionization processes. Arrows indicate transitions made by electrons.

One can identify the dominant energies from optical or electrical experiments.

To understand the properties of these centers, suppose we can arrange for the equilibrium Fermi level to rise from the valence band to the conduction band. At first practically no electrons are captured ($r = 0$). As the Fermi level rises the states corresponding to $r = 1$ begin to appear. The states ℓ of the center which correspond to the ground states in equilibrium are always more highly populated than the states ℓ corresponding to excited states, so that we can often confine attention to them. As the Fermi level rises, the ground states for $r = 2$ become more important, and there may now be hardly any centers which have captured fewer electrons. If a larger number of electrons cannot be captured, by the time the Fermi level reaches the conduction band, then states of the center with $r > 2$ can (normally) be neglected as unstable. That this is a satisfactory picture is our second approximation.

Assumptions for Nonequilibrium Statistics

The now much simplified recombination problem is still complex because of the many states available to electrons in bands and centers. A key simplification arises from the fact that it is often possible to talk about a small number of groups of quantum states: let $I\,(= 1, 2, \ldots)$ label quantum states in a group i, let $J\,(= 1, 2, \ldots)$ label quantum states in a group j, etc. Within each group it is supposed that the transitions are much more rapid than they are between groups. In that sense electrons in each group are in equilibrium among themselves. Their quasi-equilibrium is then characterized by what is called a quasi-Fermi level. The dimensionless version, obtained by dividing it by kT, is denoted by γ_i, γ_j, etc., for groups i, j, etc. That this is reasonable is our third assumption. Thus γ_c, γ_v are quasi-Fermi levels which refer to the quasi-equilibrium of the conduction and valence band, respectively, and γ_I to an I-electron center. Groups of states with different quasi-Fermi levels are not in equilibrium with each other.

Recombination problems can now be discussed by neglecting transitions within one (quasi-equilibrium) group, because they proceed at exactly the same rate as their reverse transitions. The number of transition types to be considered is thereby greatly reduced. Away from equilibrium we shall adopt eqn [3] instead of [2] in order to allow for distinct quasi-Fermi levels:

$$P(\ell, r) = \frac{\exp[r\gamma_r - \eta(\ell, r)]}{\sum_{s=0}^{M} (\exp s\gamma_S) Z_S} \qquad [3]$$

Equation [3] is not always correct, but is an approximation arising from the quasi-Fermi level assumption. Among the improved theories are, for example, the 'cascade' theories.

The assumption of a quasi-Fermi level for each state of charge of a center implies that all the excited states of an r-electron center are populated according to eqn [2].

The Main Recombination Rates

General Results and The Two-Band Case

Recombination and its converse, generation, consist of a transition of an electron from one state to another. The observed rate is the net rate of recombination and is the algebraic sum of the recombination and generation processes. During these processes both total energy and total momentum must be conserved. This is achieved by creation or absorption of photons, or phonons, excitation of secondary electrons, etc.

The transition probability per unit time, S_{IJ}, for a single-electron transition from state I in a band to state J requires that state I should be occupied, with probability p_I say, and state J should be vacant with probability q_J say. The general expression for the average rate of the transition from I to J then takes the form $p_I S_{IJ} q_J$. For the reverse process electron state J has to be occupied and state I vacant. Thus the rate of this reverse process is $p_J S_{JI} q_I$. The net recombination rate per unit volume of the process I to J can then be written as:

$$u_{IJ} = (p_I S_{IJ} q_J - p_J S_{JI} q_I) V^{-1} \qquad [4]$$

By the principle of detailed balance, this expression vanishes at equilibrium. If one puts $X_{JI} \equiv S_{IJ} p_I q_J / S_{JI} p_J q_I$, one has $u_{IJ} = p_J S_{JI} q_I (X_{JI} - 1) V^{-1}$. In equilibrium $X_{JI} \rightarrow (X_{JI})_{\text{eq}} = 1$, and the recombination rate is zero.

One can say a little more if one assumes that states I and J are in conduction or valence bands, each with a quasi-Fermi level (divided by kT to make it dimensionless). If these are denoted by γ_e and γ_h, then $p_I = [1 + \exp(\eta_I - \gamma_e)]^{-1}$ for a conduction band. For the total recombination rate per unit volume between the bands i and j one finds:

$$u_{ij} \equiv \left[\sum_{I \in i} \sum_{J \in j} p_J S_{JI} q_I \right] \left[\exp\left(\frac{|e|\phi}{kT} \right) - 1 \right] V^{-1} \qquad [5]$$

where ϕ is essentially the difference between the quasi-Fermi levels: $\gamma_e - \gamma_h$. The first factor depends on the bands involved and it has been assumed that the transition probability ratio S_{IJ}/S_{JI} is independent of the excitation.

A transition rate, when multiplied by the charge of current carriers, is a current, and when divided by the area of the surface involved, is a current density. If i and j denote the states of the conduction and valence bands of a semiconductor, excitation independence may often be assumed, and one then expects a current density proportional to $\exp(|e|\phi/kT) - 1$. This is characteristic of the current through pn junctions, metal semiconductor junctions, etc. In these configurations the Fermi level difference between the ends of the device determines the voltage across it. When radiation is involved, however, excitation dependence of some of the parameters introduced above (e.g. S_{JI}) tends to spoil this simple story.

The Case of Defects

So far we have considered only two bands. When a trap is involved matters are rather different. Because of the interactions among the electrons on a center it is not possible to talk of the same level being occupied or vacant. Consequently, identification of forward and reverse processes in terms of levels becomes impossible. Instead one deals with a center, say an r-electron center, as a whole; we then need the probability that a given center is an r-electron center. For example, the capture of an electron converts an $(r-1)$-electron center into an r-electron center. Thus the p's and q's must be replaced by more complicated expressions. It is convenient to denote u_{ij} by u_{cv} in the simple two-band case and its structure is given (with a sign change) by a recombination coefficient:

$$u_{cv} = B^S np[1 - \exp(\gamma_h - \gamma_e)] \equiv B^S np - Y^S \qquad [6]$$

using Figure 1a. Here, n and p are the electron and hole concentrations. Auger effects in Figures 1b and 1c can also be included, at least formally. Then B^S has to be replaced in eqn [6] by $B^S + B_1 n + B_2 p$. Analogous replacements are found for recombination processes involving defects.

In the simplest case of one type of localized defect one finds a steady-state recombination rate per unit volume of the form:

$$u = \frac{np - (np)_0}{\tau_{n0}(p + p_1) + \tau_{p0}(n + n_1)} \qquad [7]$$

Here τ_{n0}, τ_{p0} are parameters with the dimension of time and p_1, n_1 are parameters with the dimension of concentration. The recombination increases with the defect concentration, which is actually in the denominators of τ_{n0} and τ_{p0}. This is an old and much used result associated with the names of W Shockley and W T Read.

Radiative Transitions

Spontaneous and Stimulated Emission

Quantum theory was initiated by Planck's law for black-body radiation at temperature T. This gives the spatial energy density as a function of frequency ν in this system as

$$f(\nu, T) = \frac{8\pi\nu^2}{c^3} \frac{h\nu}{\exp(h\nu/kT) - 1} \qquad [8]$$

For low frequencies one finds the Rayleigh–Jeans law which makes [8] proportional to kT in agreement with the classical equipartition theorem. For high temperatures [8] diverges, as required.

The result [8] may also be obtained by writing

$$N = [A + Bf(\nu, T)]N_u \qquad [9]$$

for the emission rate of photons by atoms, where N_u is the number of atoms in the upper of two states which are separated by the energy $h\nu$. The first term on the right-hand side is due to the normal decay of an excited state ('spontaneous emission'). The second term refers to additional emission ('stimulated emission') induced by the radiation of frequency $h\nu$ itself.

The first factor in [8] is due to the density of states and the second factor is due to the fact that the energy is considered. If one considers the number of photons of energy $h\nu$ at temperature T one comes up with

$$N_\nu = \left[\exp\frac{h\nu - \mu}{kT} - 1\right]^{-1} \qquad [10]$$

(Bose–Einstein distribution)

Here μ is a possible chemical potential of the radiation which is non-zero only in nonequilibrium situations such as in a semiconductor laser.

In a pn junction the two bulk materials several diffusion lengths away from the junction are approximately in equilibrium even if a modest current is flowing. On one side one has then just one quasi-Fermi level, say μ_I, and on the other side one has just one quasi-Fermi level, say μ_J. Then the difference

$$\mu \equiv \mu_I - \mu_J = q\varphi \qquad [11]$$

corresponds to the applied voltage φ. This is in agreement with eqn [10], in that $\varphi = 0$ implies no current and hence thermal equilibrium is possible.

Statistical mechanics teaches one the rule that, in equilibrium, occupation probabilities of individual quantum states are always less for states of higher energies. This ensures that the total energy of a quantum system converges, the occupation probability p being a kind of convergence factor. However, if one is away from equilibrium, the above rule can be suspended and one can have population inversion.

For $h\nu = \mu$ there is trouble with [10] because the steady-state photon occupation diverges. This does not correspond to a 'death ray', but is the result of imperfect modeling; for example, the leakage of photons from the cavity may have been neglected. A formula of type [10] is also needed in connection with solar cells.

Donor–Acceptor Pair Recombination

A striking demonstration of radiative donor–acceptor transitions in GaP at low temperature (1.6 K) was revealed by sharp lines (Figure 2) at photon energies $h\nu_i$ given by

$$h\nu_i = E_G - E_A - E_D + e^2/\varepsilon R_i\,[-E] \qquad [12]$$

where R_i is the distance between the ith-order nearest neighbors.

The discrete nature of the peaks is due to the fact that the impurities involved settle in general on lattice sites so that only definite separations R_i are possible. The energy gap is E_G; the value of $E_A + E_D$ can be inferred from the experimental lines by extrapolation to $R_i \to \infty$. The energy term E is sometimes neglected.

The ZnS phosphors were the first materials in which donor–acceptor radiation was hypothesized. However, it is hard to control its stoichiometry and its impurity content, and it has relatively large carrier mass and hence relatively large impurity activation energies. In such cases spectra such as those shown in Figure 2 are hard or impossible to obtain. This applies in general to many II–VI compounds.

Quantum Efficiency

The quantum efficiency is the radiative recombination as a fraction of the total recombination. It can also be regarded as the average number of electrons produced per incident photon. Consider an intrinsic semiconductor, i.e., one in which the electron and hole concentrations are equal. Then with the notation of Figure 1 the radiative band–band recombination rate is $B^s n^2$. The nonradiative rate is $(B_1 + B_2)n^3$. We shall add another nonradiative rate, An say, proportional to the injected carrier density $n \sim p$. The quantum efficiency is then

$$\eta = \frac{B^s n^2}{An + (B_1 + B_2)n^3 + B^s n^2} \qquad [13]$$

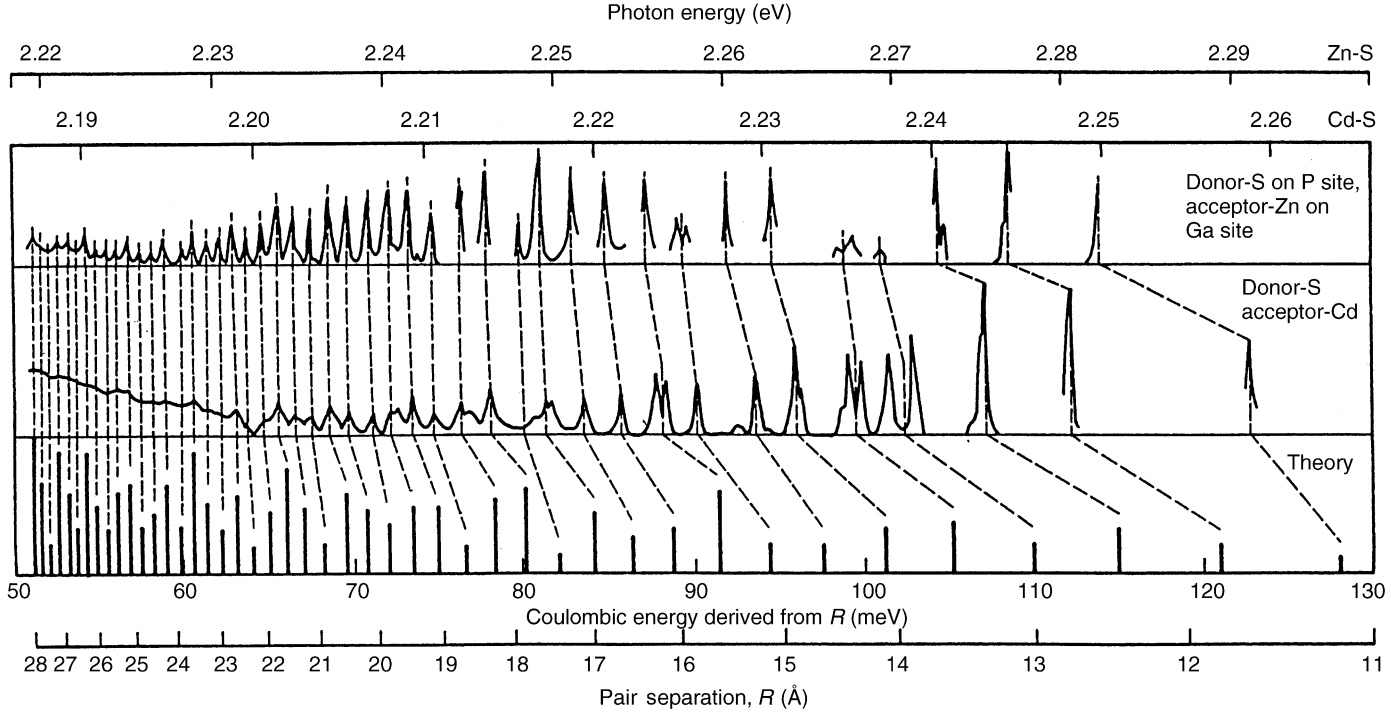

Figure 2 Comparison of the positions and intensities of the sharp line spectra at 1.6 K corresponding to both ZnS and CdS acceptor–donor pairs with the predicted pair distribution. The lower scales show the pair separation (R) and the Coulombic energy derived from R. The emission energy scales for the two measured spectra are shown at the top. Reproduced with Gershenzon M, Logan RA, Nelson DF, *et al.* (1968) *Proceedings of the International Conference on Luminescence*. Budapest, Hungary: Akademia Kiada.

Traps are here neglected, and one finds a maximum

$$\eta_{\max} = \left\{1 + \frac{2}{B^s} A^{1/2} (B_1 + B_2)^{1/2}\right\}^{-1} \qquad [14]$$

For a high-quality epitaxial AlGaAs/GaAs double heterostructure of great purity we may take

$$A \sim 0.5 \times 10^6 \text{ s}^{-1}, \quad B \sim 10^{-10} \text{ cm}^3 \text{ s}^{-1},$$
$$B_1 + B_2 \sim 10^{-29} \text{ cm}^6 \text{ s}^{-1} \qquad [15]$$

whence $n_1 \sim 2 \times 10^{17}$ cm^{-3}, $\eta_{\max} \sim 0.96$.

Detailed Balance

It is clear that the radiative recombination rate from a material should be obtainable in terms of its optical 'constants', the absorption coefficient $\alpha(\lambda)$ and the refractive index $\mu(\lambda)$. Both are functions of the wavelength. This connection can be formalized by comparing the optical absorption process with the emission process and this can be done by using the principle of detailed balance. This equates the rate of disappearance by absorption of photons with the rate of production of photons by radiative recombination. The radiative recombination rate can thus be obtained as an integral over the optical functions. This relationship, pioneered by van Roosbroeck and Shockley in 1954, has been used a great deal because the optical quantities are often known with some accuracy.

This result corresponds to balancing the rate $B^s np$ and the rate Y^s in **Figure 1a**. Analogous detailed balance results are obtainable for the other pairs of processes in **Figure 1**. Thus, the Auger recombination rate can be related to an integral over the impact ionization rate. However, this connection is less useful since impact ionization data are generally less well known than the optical absorption information.

Nonradiative Processes

Auger Effects

The Auger effect was discovered in 1925 in gases by Pierre Auger. An atom is ionized in an inner shell. An electron drops into the vacancy from a higher orbit and a second electron takes up the energy which is used to eject it from the atom. In solids the effect is roughly analogous. One of its characteristics is that it is not radiative. Since radiation is what is seen in many experiments, the Auger effect is suspected if and when there is less radiation than expected in the first place. It is rather harder to investigate than radiative transitions.

The effect has proved to be important as it limits the performance of semiconductor lasers, light-emitting diodes and solar cells, and it can be crucial in transistors and similar devices whose performance is governed by lifetimes. When heavy doping is required, as it is in the drive towards microminiaturization, its importance tends to increase, since the Auger recombination rate behaves roughly as n^2p or p^2n (see **Figure 1**) compared with the radiative rate which behaves more like np. The inverse process is impact ionization, and is important in the photodiode, the impact avalanche transit time (IMPATT) diode, and hot electron devices.

Impact ionization can be regarded as an autocatalytic reaction of order one:

$$\text{e} \rightarrow 2\text{e} + \text{h} \quad \text{or} \quad \text{h} \rightarrow 2\text{h} + \text{e} \qquad [16]$$

i.e., one extra particle is produced of the type present in the first place. This is a key feature for impact-induced nonequilibrium phase transitions in semiconductors.

In the theory one needs wavefunctions for four states of two electrons which are relevant after the many-electron problem has been reduced to a two-electron problem. In a matrix element calculation the four wavevectors imply a 12-fold integration in $\boldsymbol{k}$-space to cover all possible states of the two electrons. However, momentum and energy conservation usually reduce this to an eight-fold integration. Such a calculation is hard, for it requires (1) good wavefunctions and (2) accurate integrations.

Here we shall merely concentrate on the broad principles. In addition, the many-electron nature of the problem implies that another approximation is often inherent in the treatment apart from the use of perturbation theory. This is clear if one considers that the electron interactions are screened twice: once by an exponential screening factor and a second time by the dielectric constant. So there is some double counting, and the treatment of the effect as uncorrelated electronic transitions mediated by screened Coulomb interactions is another approximation. The collective effects that enter require more sophisticated field theoretic methods which take care of electron–hole correlations, plasmon effects and the effect of free excitons, the so-called excitonic Auger effect. These calculations broadly confirm the results obtained by the simpler methods used for energy gaps large compared with the plasmon energies,

provided the high-frequency dielectric constant is used and doping is not too heavy. Significant corrections are required for the narrow gap lead compounds, for example, and a considerable computational effort is required.

Let us now consider lifetimes for high carrier concentrations, as limited by band–band processes. They are best studied by looking at the emitted radiation. In this connection we recall the striking rise of the threshold current density J in a semiconductor laser as the material is changed from a direct material like GaAs to an indirect material, by mixing it with a compound such as GaP. Figure 3 shows this spectacular rise for $GaAs_{1-x}P_x$ at 77 K near $x = 0.38$. It is due to the drop in the radiative transition probabilities, as the substance becomes indirect, thus requiring a higher current density for threshold. So we should start with band–band processes in direct materials as most favorable for the experimentally accessible radiative transitions.

The essential point here is that the injected carrier density behaves as:

$$n_{\text{inj}} = \frac{J\tau}{qd} \sim \frac{(5\times10^{3}\ \text{A cm}^{-2})(10^{-9}\ \text{s})}{(1.6\times10^{-19}\ \text{C})(10^{-4}\ \text{cm})} \sim 10^{17}\ \text{cm}^{-3} \quad [17]$$

where J/q is the particle current density at threshold, τ is the lifetime of the carriers, and d is the thickness of the active layer. As active layers are made thinner n_{inj} increases to $10^{19}\ \text{cm}^{-3}$ or so, far in excess of the defect concentration in the (undoped) material.

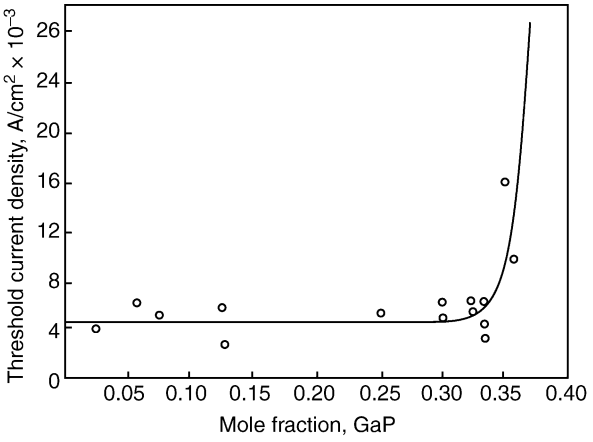

Figure 3 Lowest values of laser threshold current density at 77 K as a function of mole fraction of GaP for $Ga(As_{1-x}P_x)$ junction lasers. Reproduced from Neill CJ, Stillman GE, Sirkis MD, *et al.* (1966) Gallium arsenide-phosphide: Crystal, diffusion and laser properties. *Solid-State Electronics* 9: 735–742, with permission from Elsevier.

This brings in band–band Auger effects. These have also been invoked to explain the undesirable increase in J with temperature. Thus the interest in direct band–band Auger effects in III–V compounds is fuelled by the need for better and smaller opto-electronic devices which work at long wavelengths (1.3–1.5 μm). It matches the interest in indirect band–band Auger and impurity Auger effects in silicon due to the importance of heavy doping in VLSI (very large scale integration) and transistor technology. Figure 4 shows a typical Auger process, called CHHS, as the conduction band (C) and the split-off band (S) are involved. Two relevant states are in the heavy hole band (H). State $2'$ is referred to as the Auger carrier, as it has more kinetic energy than the others.

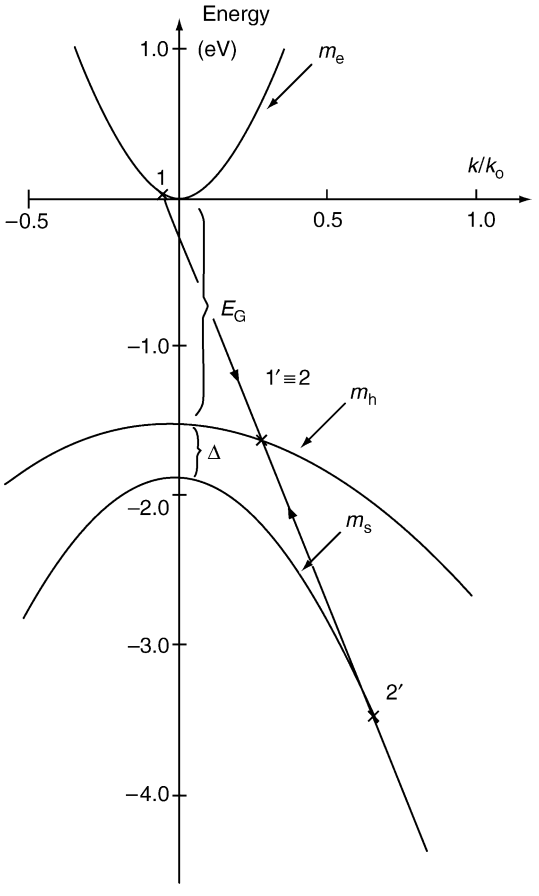

Figure 4 Conduction band, heavy hole and split-off valence bands of GaAs, all treated as parabolic with $\hbar^2k_0^2/2m_h \equiv E_G - \Delta$. x denotes a quadruplet of states for a most probable transition. The two states in the heavy hole band are not shown separately. The arrows indicate electron transitions. Reproduced from Neill CJ, Stillman GE, Sirkis MD, *et al.* (1966) Gallium arsenide-phosphide: Crystal, diffusion and laser properties. Solid-State Electronics 9: 735–742, with permission from Elsevier.

Impact Ionization

The CHHS and CHCC processes and their inverses can be written as

$$e_C + 2h_H \leftrightarrow h_s \quad 2e_C + h_H \leftrightarrow e_C \qquad [18]$$

where the suffix refers to the band. Viewed from left to right these are Auger processes. Viewed from right to left they are autocatalytic and impact ionizations.

Such processes are important for the impact-induced nonequilibrium phase transition in semiconductors. Also reaction rates with autocatalytic elements imply nonlinear equations in the concentrations and this gives rise to much interesting behavior as regards stability and bifurcation phenomena.

Momentum and energy conservation are very restrictive conditions on the four states involved in [18], and it is easily seen that they cannot normally be satisfied if in a direct band semiconductor the recombining electron drops from the band minimum to the valence band maximum. This effect raises all the kinetic energies of possible processes. The Auger electron (on the right-hand sides of [18]) must also have a minimum energy in order that the impact-ionization process can proceed. This leads to an activation energy for the process. For Figure 4, for example, and in the case of nondegeneracy, the energetic hole has a kinetic energy at threshold of

$$E_{th} = \frac{m_e + 2m_h}{m_e + 2m_h - m_s}(E_G - \Delta) \quad \text{(CHSS)} \qquad [19]$$

As the band gap increases we see that E_{th} goes up and so the Auger rate for simple parabolic bands decreases. Values of E_{th} for other transitions can be obtained from equation [19].

The total kinetic or threshold energy E_{th} can be converted to an activation energy by subtracting the basic energy which must under all conditions be part of the Auger particle energy. In the case of eqn [19] one finds for $E_G > \Delta$:

$$\begin{aligned} E_a &= E_{th} - (E_G - \Delta) \\ &= \frac{m_s}{m_e + 2m_h - m_s}(E_G - \Delta) \end{aligned} \qquad [20]$$

This can result in a strong temperature dependence in accordance with an Arrhenius factor $\exp(-E_{th}/kT)$. However, this is again lost, and the direct band–band Auger effect will certainly be important and only weakly temperature dependent, if $E_G \sim \Delta$. This can occur, for example, for InAs, GaSh and their solid solutions.

The connection between Auger processes and impact ionization has also been formalized. Of all Auger quadruplets of states in a set of nondegenerate bands, the most probable Auger transition involves the quadruplet, which yields the threshold for impact ionization. The three crosses in Figure 4 indicate such a quadruplet (the central cross represents two states).

Identification of Auger Effects

How does one know that an Auger effect has occurred? In pure but highly excited materials there is the original solid-state Auger effect which leads to a lifetime broadening of the electronic states at the band edge. For a semiconductor this effect causes fuzziness in the band edge which is a contributory factor to the overall bandgap shrinkage. The mechanism is illustrated in Figure 5, which shows how the lifetime of a vacant electron state near the band edge is shortened by the Auger processes within this band. Under normal conditions this effect is small in a semiconductor. But under degenerate conditions the effect leads by lifetime broadening to a low-energy tail in emission.

The blanket term 'Auger effect' for all Coulombically excited two-particle transitions has been used here. In semiconductor device work the 'Auger effect' has become associated with transitions in which one electron bridges an energy gap. But there is no need to limit the concept in this way. Its competition with radiative effects means that it is often detrimental and a full discussion of means of suppressing it has recently been given by Pidgeon *et al.*

More spectacular and more convincing is the *detection* of the energetic Auger electron or hole. For this purpose one may look for the weak luminescence emitted when this carrier recombines radiatively. This has been done for the band–band process in Si and for the band–impurity process

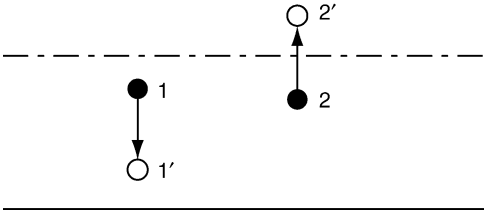

Figure 5 The filling of a state k by the Auger effect. The arrows indicate electron transitions.

in GaAs. It leads to so-called $2E_G$-emission. Its rate-limiting step is the rate of the Auger process per unit volume, $B_1 n^2 p$, which populates the high-energy level. The radiative process then proceeds at a rate $B'_1 n^2 p^2$ per unit volume with $B'_1 \sim 10^{-54}$–10^{-51} cm^9 s^{-1}.

More usual is the identification of the band–band Auger recombination mechanism from the minority carrier lifetime τ, which behaves as

$$\frac{1}{\tau_p} = B_1 n^2 \quad \text{or} \quad \frac{1}{\tau_n} = B_2 P^2 \qquad [21]$$

where B_1 and B_2 are Auger coefficients when the Auger particle is an electron or hole, respectively. A more complete expression allows also for trapping processes.

The departure from parabolic bands plays an important part for the energetic Auger particle (in state 2′). Theory shows that when this effect is taken into account, it tends to lower the band–band Auger coefficient. In fact in GaAs the CHCC process is ruled out altogether at 0 K for nonparabolic bands, suggesting that it should be an ideal material for radiative transitions. However, the possibility of phonon participation brings the effect back again, though it is still comparatively weak. The difficulty of conserving electron energy and momentum, which gives rise to the activation energies (eqn [20]) is greatly alleviated if phonons can take up some of the momentum in a direct gap semiconductor.

We have seen that the activation energy barrier against the band–band Auger effect can be overcome by a suitable disposition ($E_G = \Delta$) of the three direct bands and by phonon participation. It can also be overcome if there is an indirect minimum near a Brillouin zone edge at about half the direct energy gap.

Spin Transport and Relaxation in Semiconductors; Spintronics

M E Flatté, University of Iowa, Iowa City, IA, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Control of the generation and transport of coherent electron spin in semiconductors suggests new ways to probe the fundamentals of quantum decoherence in solids and to explore device applications that rely on coherence, including quantum computation. The focus here will be on the physical phenomena that govern spin transport and relaxation, with a particular emphasis on those phenomena that are amenable to direct manipulation. Manipulation of material properties in general has been taken to its most advanced level in the design of semiconductor electronic devices, in which operations are performed by perturbing the motion of electrons through their electric charge; hence, 'spintronics' is a term introduced to describe both the manipulation of electrons by their spin and control of their spin properties, such as g-factors.

The study of the evolution of spin coherence first requires the generation and detection of spin coherence. Here the ultrafast optical technique for generating and detecting spin-polarized populations will be emphasized. The next logical component to treat will be the persistence of spin coherence, followed by the transport of spin coherence from one region of a material to another. Finally the direct ultrafast manipulation of spin-polarized populations will be described. These components are likely to play a prominent role in any attempt to apply the fundamental physical phenomena of spin coherence to specific device technologies.

Optical Generation of Spin-Polarized Distributions

Optical pulses with definite circular polarization can be used to generate spin-polarized distributions of excited electrons in crystals. In order for this process to work one of the energy bands involved in the optical transition must be characterized by a substantial spin–orbit interaction. The selection rules for circularly polarized photons require a change in the orbital angular momentum of the electron projected along the propagation direction of the photon. For the optical transitions of an atom in free space this azimuthal orbital angular momentum l_z must increase or decrease by $\hbar$, permitting the coupling of the p-state with $l_z = 1$ to an s-state for left circular polarization, and of the p-state with $l_z = -1$ to that s-state for right circular polarization. Thus the optical selection rules pick out a particular orbital angular momentum projection.

These selection rules by themselves do not explain how spin-polarized populations are generated, for both spin directions are possible for each value of l_z. In the presence of spin–orbit interaction, however, the energy of a state with a particular l_z is correlated with the spin orientation. The six p-states, which are degenerate in the absence of spin–orbit interaction, split into two groups: one of four degenerate states and the other of two degenerate states. The higher-energy group of four degenerate states consists of two states with **L** and **S** parallel and two states with a one-third probability for **L** and **S** to be antiparallel and a two-thirds probability for **L** and **S** to be perpendicular. Thus for a transition involving the four degenerate states, a circularly polarized photon (that selects a particular initial l_z) is three times more likely to generate a carrier with spin parallel to the initial l_z than antiparallel to it.

In a solid, although full rotational symmetry is lost, the band symmetries preserve some of these selection rules. In crystals of tetrahedral symmetry, such as zincblende semiconductors, the selection rules for transitions from the valence to the conduction band are identical to the selection rules between p and s states for the atom in free space. For example, the valence heavy-hole states are those for which **L** and **S** are parallel. Thus by setting the optical photon energy to the fundamental gap, the resulting excited conduction electrons and valence holes will be spin polarized. In quantum wells, where the energy of the heavy hole is split from that of the light hole by quantum confinement (and, sometimes, strain), fully spin-polarized carrier distributions are possible. Commonly used group IV, III–V, and II–VI semiconductors have a sufficient spin–orbit interaction to permit the straightforward optical generation of spin-polarized distributions. Shown in Figure 1 are the selection rules

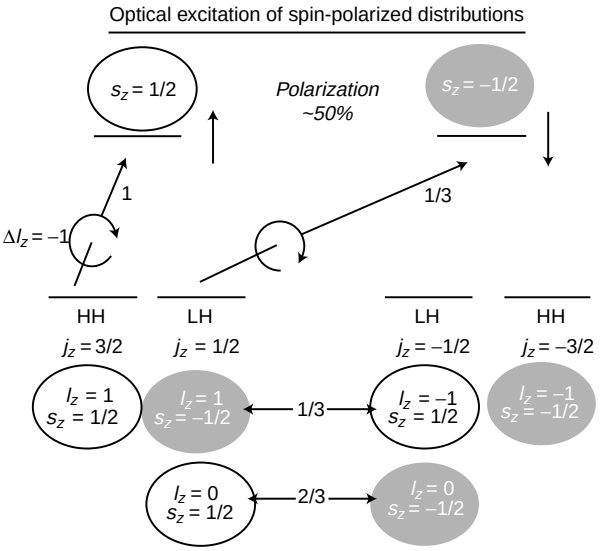

Figure 1 Selection rules for bulk zincblende crystals. Circularly polarized light changes the azimuthal orbital quantum number l_z by $+1$ or -1. Here $\Delta l_z = -1$ is shown. The orbital and spin quantum numbers for the two degenerate conduction band edge states and the four degenerate valence band edge states are shown – unshaded areas correspond to spin up and shaded to spin down. A transition with $\Delta l_z = -1$ couples one heavy-hole state to the conduction band up-spin state, and one light-hole state to the conduction band down-spin state. The orbital angular momentum of the heavy-hole state is entirely parallel to its spin angular momentum. In contrast only one-third of the light-hole state has antiparallel orbital and spin angular momentum. The rest of the light-hole state has perpendicular orbital and spin angular momentum. Thus the oscillator strength of the transition creating the conduction up-spin state is three times larger than that of the transition creating the conduction down-spin state, yielding a 50% spin polarized distribution. In quantum wells for which the heavy–light splitting is larger than the linewidth of the light source driving the transition, only the heavy-hole transition is excited and the spin polarization approaches 100%.

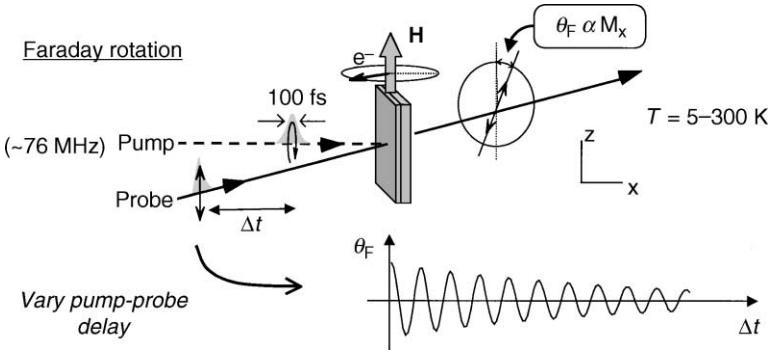

Figure 2 Diagram of the experimental geometry for time-resolved Faraday rotation. A pulse of circularly polarized light illuminates the sample, followed by a probe of linearly polarized light. The linearly polarized light can be considered as a sum of equal parts left and right circularly polarized light. The spin-polarization of the electron population (along the photon propagation direction) induces a difference in index of refraction for left and right circularly polarized light (circular dichroism). This produces a phase change between the left and right polarized components of the probe, which is measured as a rotation (θ_F) of the linear polarization direction. Monitoring the angle of rotation of the probe as a function of time directly indicates the spin polarization along the propagation axis of the photon as a function of time. Reproduced with permission from Awschalom DD, Samarth N and Loss D (eds) (2002) *Semiconductor Spintronics and Quantum Computation*. New York: Springer

which permit circularly polarized optical pulses to generate spin-polarized carriers in the conduction and valence band.

The evolution of a coherent spin-polarized population can be monitored through optical means as well. If the optical transitions used to generate the spin-polarized population are pumped hard enough, the transitions will be bleached. By measuring the polarization dependence of this bleaching the decay of the spin-polarized population can be determined. This can be done either by monitoring the transmission of time-delayed probe pulses of circularly polarized light, or by monitoring the rotation angle (Faraday rotation) of a pulse of linearly polarized light. The first of these depends directly on the imaginary component of the spin-polarized dielectric function, whereas the second depends directly on the real components. Shown in Figure 2 is the geometry for observing Faraday rotation from a spin-polarized distribution in the presence of an applied magnetic field perpendicular to the spin polarization.

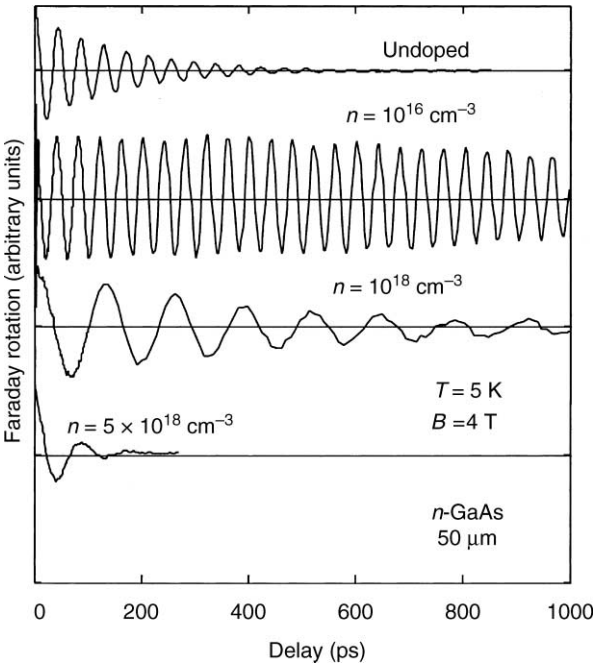

Figure 3 Time-resolved Faraday rotation measurements on bulk GaAs at several doping levels, indicating a sensitive doping dependence of the transverse spin coherence time T_2. T_2 for ideal doping densities can exceed 150 ns at 5 K. The magnetic field is 4 T, and the sample is 50 μm thick. Reproduced with permission from Kikkawa JM and Awschalom DD (1998) Resonant spin amplification in *n*-type GaAs. *Physical Review Letters* 80: 4313–4316.

Mobile Electron Spin Time Evolution: Decoherence and Precession

Two natural phenomena in the time evolution of a coherent spin-polarized population are decay of that population (decoherence) and rotation of the macroscopic magnetization in the presence of an applied magnetic field (precession). The time-scale of decay of the spin coherence can be very much longer than time-scales for the decay of other coherent phenomena in solids. Typical orbital coherence times, for example, are 100 fs, whereas spin coherence times can exceed microseconds. In Figure 3 are shown time-resolved Faraday rotation data for three bulk GaAs

crystals with different doping levels. The oscillations are characteristic of the spin precession, and the oscillation frequency is the Larmor frequency of the electron spin in this crystal. The crystal with the middle doping level, 10^{16} cm^{-3}, has oscillations that persist for the longest time, and therefore this material has the longest spin coherence time.

The dominant mechanism for the decay of these spin polarized distributions works via the same spin–orbit interaction that permits the generation and detection of these spin-polarized distributions. For mobile electrons in homogeneous environments, the mechanisms of spin coherence relate to the crystal momentum-dependence of the eigenstates of the electronic system. Because of time reversal invariance the electronic states with zero momentum (at the Γ point in the Brillouin zone) are doubly degenerate. The electronic states for momentum $\mathbf{k}$ near the Γ point occur in nearly degenerate pairs. Although it is common usage to refer to these eigenstates as degenerate spin eigenstates (correct in the absence of spin–orbit interaction), with spin–orbit interaction the states are not spin eigenstates and are not necessarily degenerate. As a consequence, when a spin-polarized carrier is scattered by ordinary, non-spin-dependent scattering from one momentum state $\mathbf{k}$ to another $\mathbf{k}'$, and then back again to $\mathbf{k}$, the effective orientation of the carrier spin will have rotated by an angle dependent on the intermediate momentum state $\mathbf{k}'$. For a population of carriers in thermal equilibrium this process will lead to misorientation of the individual spin moments from the mean, and thus a decoherence of the spin population. This process is characterized by an increasing decoherence rate with increasing orbital scattering. Thus the dirtier a material is made, the faster the spin orientations decohere.

In crystals with inversion symmetry the pairs of nearly degenerate states are precisely degenerate. Lack of inversion symmetry, and the consequential energy splitting, can be viewed as an effective (crystal) magnetic field, in which the approximate spin eigenstates precess. The magnitude and direction of this effective field depends on the orbital momentum $\mathbf{k}$, and because of time reversal invariance, the effective fields for $\mathbf{k}$ and $-\mathbf{k}$ are opposite. Thus an initially spin-polarized population will dephase due to experiencing different effective magnetic fields. Ordinary spin-independent scattering can now be seen as randomly changing the precession axis for the spin in this effective field. Once the information about the precession axis orientation has been lost the dephasing is not reversible and the spin orientations have decohered. As the precession angle increases linearly between scattering events, the longer the time between such scattering events the faster the spin population decoheres. Thus for this process the cleaner a material is made, the faster the spin orientations decohere. This precessional decoherence process dominates for mobile conduction electrons in bulk and quantum-well III–V semiconductors near room temperature.

The influence of the spin–orbit interaction is far stronger for the valence electrons than the conduction electrons for two reasons. First, as the effective magnetic fields come from relativistic transformations of internal electric fields, and the electric fields are largest near the nucleus, the valence electrons, which are closer to the nucleus than the conduction electrons, experience a stronger spin–orbit interaction. Second, the valence electrons have a dominant p-like character, whereas the conduction electrons have dominant s-like character (and thus lack orbital angular momentum to be coupled to the spin). Thus the spin coherence times of valence electrons (or holes) are commonly much shorter than the coherence times of the conduction electrons. Spin-flip exchange between conduction electrons and valence holes can therefore be the dominant source of decoherence for conduction electrons. This process can dominate at low temperatures in clean III–V semiconductors, and even up to room temperature in III–V quantum wells grown along the unusual (110) growth direction.

As a consequence one would expect the spin coherence times of electrons in n-doped semiconductors to be longer than those of electrons in p-doped or undoped semiconductors (in which excess holes must also be optically generated). This expected trend is present in Figure 3, for the n-doped materials have longer spin coherence times than the semi-insulating material. However, as the effect of the spin–orbit interaction increases with increasing momentum $\mathbf{k}$, the spin coherence times of the more heavily doped material are shorter than those of the lightly doped material. The doping corresponding to the longest spin coherence times may lie near the metal–insulator transition, although the theory of spin coherence times on the insulating side of that transition is not as well developed as on the metallic side.

Transport and Manipulation of Spin Coherence

An essential component of the motion of spin coherence in semiconductors is the response of carriers to electric fields. Outside of very unusual electronic states in semiconductors, such as the quantum Hall state, there is no spin–charge

separation of elementary carriers. The carriers in the semiconductors will move under the influence of an electric field, and if they happen to be spin-polarized, then a spin current will exist. Although there are numerous possible regimes of spin transport (at least as many as there are regimes of charge transport), only two will be presented here, both in the low-field diffusive limit.

Mobilities and diffusion constants are the material properties that describe the low-field charge transport in a homogeneous material. Spin transport can be described similarly, and the spin mobility and diffusion constant can be related to those of charge motion. The relationship between the two emerges from the nature of carrier packets that can be maintained under low-field conditions. Deviations from local charge neutrality cause very large space-charge fields in the semiconductor, and thus under low-field conditions approximate local charge neutrality must be maintained. Shown in Figure 4 are charge and spin packets in an n-doped semiconductor. The charge polarization packet, incorporating extra conduction electrons and valence holes, is shown in Figure 4a. The electron spin polarization packet shown in Figure 4b is qualitatively different from the charge packet as well as the hole spin polarization packet (shown in Figure 4c). Only the electron spin polarization packet does not incorporate both conduction electrons and valence holes.

The difference in packet structure profoundly changes the mobility and diffusion properties of the packet. For packets consisting of both electrons and holes the low-conductivity carrier species dominates the packet motion (in this case, the holes). For the electron spin packet, however, majority carriers dominate the packet motion. Thus motion of this spin packet is very rapid, and also sensitive to the higher Fermi temperature of electrons relative to holes. Experimentally this has been seen by optically creating a local spin-polarized packet of conduction electrons (an electron spin packet) in a thin sample of n-doped GaAs. The application of a lateral electric field drags that spin packet, and an optical probe measures the transport distance (thus the mobility) and the packet spread (yielding the diffusion constant). Such an approach is very similar in concept to the electrical probe of charge packet motion developed by Shockley and Haynes to measure minority hole mobility and diffusion in n-doped Ge.

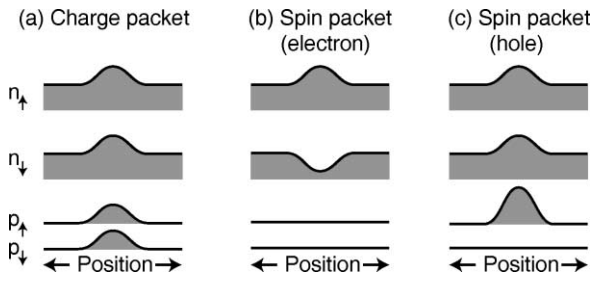

Figure 4 Inhomogeneous carrier packets in n-doped semiconductors in the low-field regime. The charge polarization packet (a) is constructed of approximately equal numbers of electrons and holes. The electron spin polarization packet (b) can be constructed without any excess holes, whereas the hole spin polarization packet (c) requires both excess electrons and excess holes. The presence of minority carriers in a packet significantly alters the mobility and diffusion properties of the packet.

The picture of approximately charge-neutral packets is very helpful for describing spin motion in homogeneous materials, but most semiconductor devices are based on inhomogeneous configurations of semiconducting material. For example, the most ubiquitous charge-based semiconductor device is the p–n diode, whose nonlinear current–voltage characteristics have been used as building blocks for numerous other devices. Such devices rely on the ability of a current to traverse an interface between two dissimilar materials – either different in doping density or different in host structure. Experiments in metallic ferromagnetic systems indicated that, whereas charge current was easily passed from one ferromagnetic metal to another through an interface, the same was not always true for the spin current. Differences in band structure or interface roughness are usually expected in such systems to strongly diminish the efficiency of spin current transfer across the interface.

Semiconductors, however, offer a possible new regime. The bulk band structures of most III–V semiconductors are very compatible – the variations in bandgap may be substantial, but the orbital wavefunctions are very similar. Current growth techniques permit the fabrication of atomically smooth interfaces between two semiconductors, so long as the lattice constants are almost identical. Thus one might expect the spin current to be transferred across such interfaces without tremendous degradation.

The transfer process for spin current across the GaAs/ZnSe interface has been investigated in detail. Here the ZnSe material was n-doped, and GaAs layers that were n-doped, p-doped, and semi-insulating were investigated. Electron spin polarization was generated optically in the GaAs layer. For n-doped GaAs in the absence of an electric field only a small signal for spin-polarized electrons in the ZnSe was detected. An applied electric field, however, which drove the electrons within the GaAs towards the interface, produced a substantial spin-polarized population in the ZnSe. This indicates that spin-polarized packets can be created in one

semiconductor, and then controllably moved into a second semiconductor with an applied electric field. This ability may become a key component of manipulating spin in semiconductors.

One reason the p–n diode is a paradigm of charge-based semiconducting electronics is that it exhibits the crucial phenomenon of minority spin injection. Manipulation of minority spin injection permits great control of charge current, for its amplitude is very sensitive to barriers (such as those introduced by gates). Spin-polarized minority carrier injection has not been shown yet experimentally, however the complementary process of minority carrier extraction has. This process corresponds to optically generating spin-polarized electrons in p-doped GaAs, where the electrons are minority carriers. The built-in electric field of the p–n junction drives these electrons out of the GaAs into the n-doped ZnSe with great efficiency. Thus one may imagine that spin-polarized minority carrier injection is plausible in these systems.

A hybrid of these two situations is the spin-polarized light-emitting diode. Here spin-polarized carriers (either electrons or holes) are electrically injected into the insulating region of p–i–n structure. In the insulating region they recombine with unpolarized carriers of the other species and emit light. Due to the selection rules described before, the emitted light is circularly polarized, and the degree of circular polarization is an indication of the spin-polarization of the recombining carriers. This device demonstrates that large numbers of spin-polarized carriers can be accumulated in the insulating region, although the spin-polarized carriers are not minority carriers.

Methods of manipulating electron spin coherence externally without electric fields are also under investigation. One demonstrated technique relies on the shift of energy levels in a semiconductor under illumination by laser light with frequencies below the fundamental bandgap. When the laser light is circularly polarized this 'ac Stark effect' shifts the energy levels of spin-up states and spin-down states differently, generating an effective magnetic field. Rotations of electron spin by angles greater than $\pi/2$ have been demonstrated in this ultrafast effective magnetic field in semiconductor quantum wells.

Transfer of Spin Coherence from Mobile Electrons to Other Spin Systems

Another fundamental phenomenon in spin coherence is the transfer of spin coherence from one system to another. If one spin system has an extremely long coherence time, this transfer can be viewed as establishing a reservoir of spin coherence that can be drawn on at later times. Explorations of transfer phenomena have focused on establishing spin coherence in a system that is coupled to the conduction electrons, such as core electron polarization or nuclear polarization. The polarization of these other spin systems can be detected because, when polarized, they exert an effective field on the conduction electrons. For example, when the nuclear system is polarized it exerts an effective field on the electrons through the hyperfine coupling.

It is also possible to polarize these other systems indirectly through their interaction with the conduction electron system. When the conduction electron system is driven far from equilibrium by optically pumping the spin polarization, the coupled spin systems also become spin polarized. In the case of the nuclear spin system this effect is the Overhauser effect. While continually generating conduction electron spin polarization with optical pumping the polarization of the nuclear system begins to rise with a time-scale characterized by the coupling between the nuclear spins and the conduction electron spins (hyperfine coupling). Because of the substantial difference between the nuclear spin coherence times parallel to and perpendicular to the applied magnetic field, the effective nuclear polarization is generated parallel to the applied magnetic field independent of the orientation of the conduction electron spin polarization. In bulk GaAs at 5 K the percentage polarization achieved was a few per cent, yielding an effective field through the hyperfine interaction of ~ 0.4 T. These nuclear polarizations and effective fields are increased over an order of magnitude in certain quantum wells, suggesting that nanostructure design can be used to control the effective fields. The induced nuclear polarization persists for time-scales characteristic of the nuclear longitudinal spin coherence time, on the order of minutes. If the optical pumping is turned off, the conduction electron spin polarization decays away rapidly, whereas the nuclear spin polarization persists for time-scales characteristic of the nuclear longitudinal spin coherence time, on the order of minutes. This nuclear hyper-polarization, and its manipulation through an optically pumped time-dependent conduction electron spin polarization, suggests a possible general technique of ultrafast all-optical nuclear magnetic resonance in solids.

A similar spin-coherence storage effect has been obtained for core electron polarization in Mn-doped ZnSe quantum wells. Again, the optically pumped

conduction electron spin polarization generates a nonequilibrium spin polarization of the paramagnetic core electron spins (3d in the case of Mn) through the core-conduction electron coupling. This core electron spin polarization persists long after the conduction electron spin polarization (and, in undoped systems, long after the conduction electron density) has decayed away. The magnetic polarization of the paramagnetic Mn spins dephases over the very long time-scales determined by spin–lattice relaxation, and thus is an interesting avenue towards information storage.

The above systems are not ferromagnetic – the spin systems involved in the process are paramagnetic spin systems coupled to the conduction electrons, which are 'super-polarized' through the conduction electron spin polarization. An alternative approach to manipulating the conduction electrons has recently been demonstrated using a thin layer of a ferromagnetic material placed on top of n-doped GaAs. Here the presence of this ferromagnetic material, even if only a few nanometers thick, leads to a remarkable enhancement of the nuclear spin polarization in the GaAs. For example in the presence of a mere 1000 G applied magnetic field, the ferromagnetic layer generates an effective field on the electrons from the nuclei of up to 9000 G. This effective field also depends on the orientation of the magnetism in the ferromagnetic layer. This intriguing effect has yet to be fully explored, but may yield a new type of magnetic 'gate' on the mobile electrons in a semiconductor without a direct form of electrical spin injection.

The Future of Semiconductor Spintronic Devices

Semiconductor charge-based electronics (e.g., transistors and integrated circuit chips) and magnetoelectronics (e.g., hard disk read heads) are two of the most successful electronic technologies of the twentieth century. A union of elements of these two technologies is anticipated in the area of semiconductor spintronics. Immediate approaches involve placing hybrid magnetic elements within known semiconductor devices. Semiconductor spintronic devices, however, are unlikely to compete with the most successful devices from each of these two areas – the semiconductor transistor is an extremely effective and efficient device, as is the magnetoelectronic hard disk read head. As has occurred with many other new technologies perhaps the most important applications of semiconductor spintronics have not even been envisaged yet.

Despite this, one significant application without a dominant technology suggests itself – that of quantum computation. Recent advances in the theoretical understanding of quantum information technology, including novel algorithms, error-correcting codes, and plausible scalable device architectures, suggest that calculations involving quantum mechanical coherent states are possible. Here the extremely long spin coherence times in semiconductor systems, and the demonstrated ability to manipulate that coherence on ultrafast optical times, indicate that spins in semiconductors (whether electron or nuclear) may constitute a good basis for a physical realization of a quantum computer.

Surface Photovoltage Spectroscopy of Semiconductors

L Kronik, Weizmann Institute of Science, Rehovot, Israel

Y Shapira, Tel-Aviv University, Tel-Aviv, Israel

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Surface photovoltage spectroscopy (SPS) is a well-established contactless technique for semiconductor characterization, which relies on analyzing illumination-induced changes in the surface voltage. SPS traces its origins to the pioneering work of Brattain and Bardeen in the early 1950s, and was extended into a powerful spectroscopic tool by Gatos, Lagowski and Balestra in the early 1970s. It has been used as an extensive source of surface and bulk information on various semiconductors and semiconductor interfaces. In the following, we present the basic theory behind SPS, its experimental setup, and a range of its applications.

Principles of Operation

In general, a surface is defined as a boundary of media with different physical properties. The periodic structure of an ideal crystalline semiconductor results in the appearance of allowed energy bands separated by forbidden energy gaps. In particular, semiconductors are characterized by a nearly full 'valence band', separated by a forbidden bandgap from a higher lying, nearly empty 'conduction band.' Electron transport takes place within the latter and hole transport takes place within the former. The mere termination of this periodic structure at the surface, as well as the chemical changes in the surface associated with this termination, allow for the formation of surface-localized electronic states within the semiconductor bandgap. Electrons or holes in these local states are referred to as 'trapped carriers', as opposed to the 'free carriers' in the conduction and valence bands.

The appearance of surface-localized states induces charge transfer between bulk and surface in order to establish thermal equilibrium between the two. The free carrier density in the vicinity of the surface therefore deviates from its equilibrium value in the bulk. This results in a surface space charge region (SCR), which is electrically non-neutral, implying a nonzero electric field in it and therefore a potential drop across it. Thus, even under equilibrium conditions the surface potential, V_s, is different from the electric potential far away in the bulk. As a specific example which illustrates these concepts, consider an n-type semiconductor with a depleted surface. The majority carriers are electrons and some of them have been trapped in surface states, such that their concentration in the vicinity of the surface is smaller than its equilibrium value but larger than that of the holes (see **Figure 1a**). The potential drop across the SCR is manifested by the bending of the semiconductor bands, which is such that electrons are repelled from the surface and holes are attracted to it, due to the trapped surface electrons. We note that, by definition, the energy band edge is lower the higher the electrical potential, so that a positive V_s corresponds to downward-bent bands.

Generally, the photovoltaic effect comprises an illumination-induced change in the equilibrium potential distribution and is typically the result of some charge transfer and/or redistribution within the device due to the incident illumination. This is the basic principle behind devices ranging from photodiode detectors to photovoltaic solar panels. A specific variant of the photovoltaic effect is the *surface* photovoltaic effect, which is at the center of this text. It is important to note that the formation of a surface photovoltage (SPV) occurs only if carrier photogeneration *per se* is followed by net charge redistribution. Usually, no significant driving force for such redistribution is found beyond the SCR and the underlying bulk remains quasineutral. Thus, we are interested primarily in the surface SCR.

The SPV mechanism depends strongly on whether the incident photon energy is larger or smaller than the semiconductor bandgap (denoted below as the super-bandgap and sub-bandgap, respectively). Dominant SPV mechanisms are demonstrated below for a depleted n-type surface. The dominant mechanism by which super-bandgap illumination results in surface photovoltage generation is shown in **Figure 1b**. The electric field in the SCR causes excess electrons to be swept away from the surface and excess holes to be swept towards it. This serves to reduce the density of surface-trapped electrons and decreases the band-bending. In a second mechanism, shown in **Figure 1c**, either electrons or holes are preferentially trapped at surface defects. This effectively charges the surface and thus modifies the

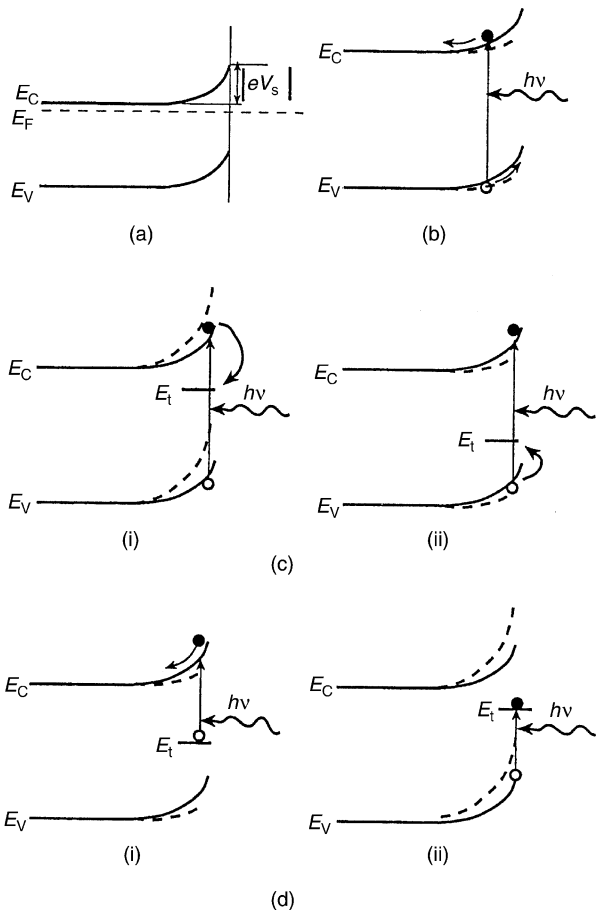

Figure 1 Schematic band diagrams of the surface space charge region at a depleted n-type semiconductor surface under different conditions: (a) thermal equilibrium; (b) super-bandgap illumination with carrier separation under an electric field; (c) super-bandgap illumination with preferential trapping of: (i) electrons, (ii) holes; (d) sub-bandgap illumination with excitation of trapped: (i) electrons, (ii) holes. In all diagrams, solid and dashed lines indicate band positions in the dark and under illumination, respectively. Straight arrows denote carrier generation and curved arrows denote carrier trapping. Adapted from Gal D, Mastai Y, Hodes G and Kronik L (1999) Bandgap determination of semiconductor powders via surface photovoltage spectroscopy. *Journal of Applied Physics* 86: 5573. Reproduced by permission of the American Institute of Physics.

surface potential. This second mechanism is usually apparent in bulk samples only if the equilibrium surface band-bending is fairly small, but increases in importance in polycrystalline materials with decreasing crystallite size, because of the increasing surface to volume ratio.

The most common mechanism for sub-bandgap SPV involves the direct modification of the surface charge, and hence potential, by excitation of trapped carriers, as shown in Figure 1d. Illumination by photons with energy $h\nu > E_c - E_t$ may produce electron transitions from a surface state at an energy E_t into the conduction band, where they are quickly swept to the semiconductor bulk by means of the surface electric field. Hence, the negative surface charge is reduced and the band-bending decreases. Conversely, illumination by photons with energy $h\nu > E_t - E_v$ may produce electron transitions from the valence band into a surface state situated at an energy E_t above the valence band maximum, E_v (which are equivalent to hole transitions from the surface state to the valence band). Such transitions increase the surface negative charge and therefore the surface band-bending. For a SPV to develop in this case, it is necessary to have a significant diffusion of the excess holes into the bulk and/or a significant recombination of electrons and holes inside the SCR, as there is no field-assisted driving force of holes into the bulk.

A typical SPV spectrum shows the SPV as a function of incident photon energy. Its most important features – the ones to watch for when attempting to interpret an SPV spectrum – are the sharp slope changes ('knees') associated with an abrupt onset of an additional carrier excitation mechanism. Consider, as an illustrative example, the top SPV curve in the right-hand part of Figure 2 (the rest of the figure is discussed below). In this curve, two 'knees' are shown. The first 'knee' (marked by an arrow) occurs at sub-bandgap photon energies and corresponds to the onset of carrier excitation from surface states (as in Figure 1d). The second 'knee' occurs in the vicinity of the bandgap energy and corresponds to the onset of band-to-band carrier excitation (as in Figure 1b,c). The proper interpretation of the energy position of these 'knees', their sign (negative or positive SPV change), and the relation of both to the SPV mechanism at work, is elaborated below in the 'Applications' sections.

So far, our discussion has been devoted solely to a study of semi-infinite, uniform bulk samples. However, actual semiconductor samples may be thin, i.e., not much larger than the diffusion length and/or the absorption length, so that excess carriers may be present near their back part as well. Many optically and electronically interesting structures (advanced detectors, transistors, lasers) consist of a multilayer structure, which has several buried interfaces.

Any change in the potential drop across a buried surface will also be measurable at the front surface, because potential drops are additive. For example, the photo-induced potential drop across a photodiode is measured at its contacts, which can be many microns away from its active region. Thus, the sensitivity of SPV measurements to a certain region in the semiconductor is limited only by the

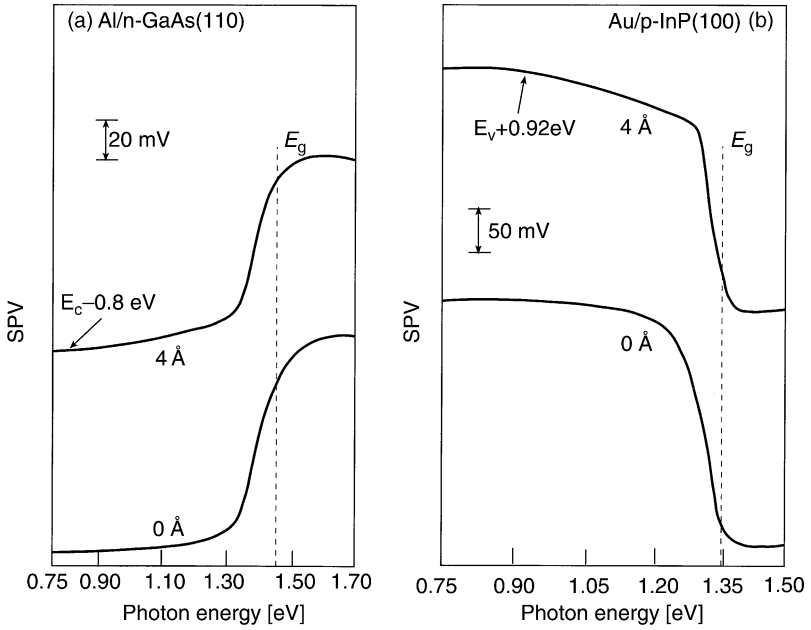

Figure 2 SPV spectra of: (a) an n-type GaAs(110) surface, UHV cleaved (top curve) and with an Al overlayer (bottom curve); (b) a p-type InP(110) surface, UHV cleaved (top curve) and with an Au overlayer (bottom curve). Arrows denote the onset of optically induced transitions and labels denote the corresponding defect level. absorption length of the photons, i.e., by the possibility of introducing an excess of free carriers in the region of interest.

Experimental Details

SPV measurements are nontrivial because the surface potential is a *built-in* potential, rather than an external potential. In other words, the surface potential is not equal to the difference in Fermi levels between the front and back surfaces. Therefore, it cannot be simply measured using some form of voltmeter. Moreover, in the case of a free surface, the application of any contact to indirect electrical measurements of the built-in voltage (e.g., current–voltage or capacitance–voltage analyses) will invariably alter the surface properties and hence the quantity under measurement. Consequently, most of the prevalent techniques for measuring the surface potential (or at least changes of it upon illumination) are based on capacitive coupling schemes that do not require a direct electrical contact.

The two most commonly used methods rely on bringing a metallic probe close to the free surface, but never touching it, thus forming a parallel-plate capacitor. An alternating current, from which surface potential changes can be calculated, is then excited by (a) vibrating the metallic probe, which results in alternating capacitance, or (b) using 'chopped' illumination. The two approaches are known as the Kelvin probe and the ac-SPV schemes, respectively. In principle, they provide similar information, but their somewhat different physical principles result in several relative strengths and weaknesses, which make the method of choice application-dependent. In a nutshell, the Kelvin probe is more suitable for following phenomena with large time constants (in particular surface states with long relaxation times) and does not perturb the true band-bending of the free surface. The ac-SPV technique is more suitable for following fast relaxation phenomena, allows for a systematic modification of the surface band-bending in the dark as an extra degree of freedom, and does not require an ohmic back-contact.

Both Kelvin probe and ac-SPV measurements may also be employed in a scanning mode, which allows for recording lateral variations in the SPV, by scanning a small probe or a well-focused light beam, respectively, across the surface. Both approaches are typically limited to a lateral resolution roughly of the order of $\sim$1 μm. SPV measurements can also be performed by a limited modification of two high-resolution techniques for topographic

mapping of surfaces that have emerged in the 1980s: scanning tunneling microscopy (STM) and atomic force microscopy (AFM). This opens new horizons for SPV mapping with a resolution on the nanometer scale or even the atomic scale.

A schematic view of a complete, generic SPS setup is given in Figure 3. The sample under study is typically placed inside a metallic box, which serves as both a dark box and a Faraday cage. This box must be such that it effectively includes the probe.

Clearly, for spectroscopic purposes one needs to generate the SPV signal using a broadly tunable light source. The default choice would therefore be the use of a 'white-light' source in conjunction with a monochromator. Because the typical super-bandgap absorption coefficient is typically orders of magnitude larger than the sub-bandgap coefficient, SPS is vulnerable to the spurious contribution of high-order diffraction peaks and stray light. Use of a monochromator where these effects are as small as possible is therefore highly recommended. For some applications, use of an auxiliary light source (e.g., white light, laser light, ultraviolet light, etc.) allows for a 'photobias' of the system and/or for additional quantitative analysis.

The actual recording of an SPV spectrum is coordinated by a real-time computer program. This program controls the monochromator motor and thus wavelength changes, operates the control electronics of the probe, reads the measurement results by interfacing with the probe read-out electronics via an analog-to-digital converter, and finally stores the obtained spectrum for subsequent display and analysis.

New York: John Wiley and Sons, Inc.

Applications I: Uniform Semiconductors

An elementary application of SPS is the approximate determination of the semiconductor bandgap. This determination is based on the large increase in absorption coefficient near the bandgap energy, E_g, found in most semiconductors. This increase brings about a significant change of the SPV signal, which is easily identified as a sharp change in slope of the SPV curve and is often the most significant one in a given spectrum. An example is shown in Figure 2, where the slope changes related to the bandgaps of GaAs and InP are clearly identified. Indeed, the bandgaps of most known semiconductors have been analyzed using this approach.

The use of SPS for extraction of E_g is at heart nothing more than an emulation of an absorption spectrum. However, as opposed to, e.g., transmission spectroscopy, SPS does not require light collection. It can therefore be performed on arbitrarily thick samples (or on layers sandwiched within a hetero-structure – see below) and does not require the sample to be removed from the substrate or grown on a transparent one. It is also inherently insensitive to reflection and scattering and is thus eminently useful for micro- and nanocrystallites.

One must bear in mind that the value of E_g obtained from an SPS plot by inspection is only approximate. Indeed, detailed experimental comparisons between SPV and absorption spectra reveal that the two are often similar, but never identical. Thus, the nominal bandgap is nearly always found within the onset of the largest SPV signal, but is usually relatively broad, the exact position of E_g within it is by no means obvious, and the error in E_g is often ~ 0.1 eV. However, it has been shown that this error can be reduced significantly – often by one to two orders of magnitude – by a careful quantitative analysis of the experimental data.

We now turn our attention to determining the type (p or n) of the semiconductor. This may be achieved with the help of the sign of the knee associated with the onset of the super-bandgap SPV. Most semiconductor surfaces are depleted, which means that the bands of p-type semiconductors are bent downwards towards the surface, whereas the bands of n-type semiconductors are bent upwards. Since super-bandgap illumination typically tends to decrease the surface band-bending, this would result in a positive SPV in n-type semiconductors and a negative SPV in p-type semiconductors. For example, the SPV spectra of n-type GaAs and p-type InP, shown in Figure 2, clearly feature opposite onset signs which obey the above rules.

While in many cases the type of the semiconductor is known a priori, this is not always the case and SPS can become very useful in determining the semiconductor type. For example, SPS was used for fast and nondestructive verification of the semiconductor type in GaN films, where the p-doping is known to be nontrivial and subject to compensation by its native n-type doping.

We note that under conditions where the SPV is dominated by trapping of carriers, as shown in Figure 1c, the sign convention described above clearly does not apply. For example, etched CdSe quantum dot films were found to exhibit a p-type response in a humid ambient and an n-type response in a dry ambient, on account of preferential trapping of holes or electrons in a dry or humid ambient, respectively.

A key strength of SPS is in the determination of the energy position and type of surface states. Because photons of sufficient energy may excite charge carriers from a surface state to a band or vice versa, we expect a knee in the SPV spectrum whenever the photon energy exceeds the threshold energy of a certain transition. If the latter involves excitation of electrons from the surface state to the conduction band (Figure 1d(i)),a positive change in the surface charge is induced, and hence a positive SPV is expected. Conversely, excitation of holes to the valence band (Figure 1d(ii)) makes the surface charge more negative and a negative SPV is expected. Thus, the combination of the SPV threshold energy and slope sign makes the determination of the approximate position of the surface state within the bandgap possible.

As an illustrative example, consider how SPS can be used to monitor metal-induced surface states, as shown in Figure 2. After cleaving in ultrahigh vacuum, neither GaAs nor InP surfaces display any knees associated with deep surface states, as expected for these surfaces. However, upon deposition of a very thin metallic overlayer, distinct sub-bandgap knees emerge. These knees, associated with positive and negative SPV changes at the Al/GaAs and Au/InP interfaces, respectively, indicate the formation of surface states situated ~0.8 eV below the conduction band edge and ~0.92 eV above the valence band edge, respectively.

Because SPS is contactless and nondestructive, it can be applied not only to clean surfaces, but also to real ones, in practically any ambient. This makes SPS highly suitable for a direct correlation of surface electronic structure with chemical treatments. One such area of active research is the study of surface passivation treatments. An illustrative example, in which the passivating effects of various liquids on a specific p-InP surface (denoted as (100)) was studied *in situ*, is shown in Figure 4. The negative

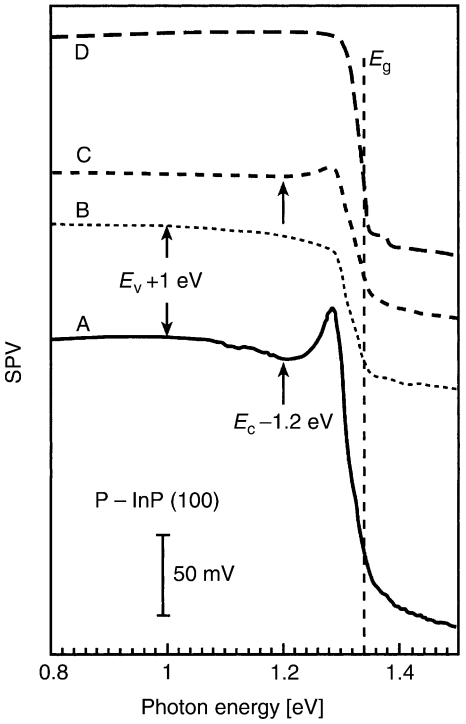

Figure 4 SPV spectra of the p-InP(100) surface in air and after successive immersion in (from top to bottom in the lower energy part): A – 18 MΩ H_2O; B – 0.4% HF; C – 30% H_2O_2; D – a 1.3 M Na_2S solution. Adapted from Bastide S, Gal D, Cahen D and Kronik L (1999) Surface photovoltage measurements in liquids. *Review of Scientific Instruments* 70: 4032. Reproduced by permission of the American Institute of Physics.

SPV change at ~1.3 eV found in all spectra shown is clearly due to the onset of band-to-band transitions in the InP sample, with its sign indicating a p-type sample, as appropriate. The SPV spectrum of the water-exposed sample (which is similar to that obtained in air (not shown)) features two surface states: the negative SPV slope change, at ~1 eV, is due to a photo-induced population of a surface state situated ~1 eV above the valence band edge. The positive SPV slope change at ~1.2 eV is due to a photo-induced depopulation of a surface state situated ~1.2 eV below the conduction band edge. Interestingly, exposure to HF eliminates the latter state, but not the former. The opposite is true for exposure to H_2O_2. Finally, exposure to a Na_2S solution results in removal of both surface states, in agreement with the known passivating action of this solution. This is just one example of many illustrating the strength of SPS for revealing the link between chemical/physical treatments and device-affecting electronic properties, already at the material level.

While we have so far considered only surface states, SPS is sensitive to bulk states too, as long as charge excited from or trapped in them can be separated (typically under the electric field of a space charge region). Accordingly, SPS has been used for studying, e.g., Cr-related defects in GaAs or Fe-related defects in InP. The simplest distinction between surface and bulk states in SPS is obtained by examining whether the pertinent spectral feature disappears after surface (e.g., etching) or bulk (e.g., doping) treatment, respectively.

We note that in recent years, SPS has also been applied successfully along the lines outlined here for the study of bandgaps, doping type, and surface and bulk defects in the emerging field of organic semiconductors and organic treatments of semiconductors, as well as for nanostructures, such as fullerenes and nanotubes.

Additional, quantitative analyses of the SPV spectra allow for a determination of densities, thermal and optical transition rates, and the spatial site of gap states. Such analyses are usually based on the SPV response to a systematic modification of one or more external parameters, e.g., time (for transient responses), illumination intensity, temperature, etc.

Applications II: Multilayer Structures

Beyond the study of surface properties, the application of SPS to heterojunctions, multilayer structures, and actual device structures has been most rewarding in recent years. The SPS of multilayer structures is illustrated by Figure 5. This figure features the SPV spectra of a ZnO:Al/ZnO/CdS/Cu(In,Ga)Se_2 layered structure, used for the fabrication of thin-film solar cells. Distinct spectral knees at ~1 eV, ~2.4 eV, and ~3.1 eV, corresponding to the bandgaps of Cu(In,Ga)Se_2, CdS, and ZnO, respectively, are clearly observed. The unequivocal identification of all three bandgaps confirms the above-mentioned theoretical prediction of SPS sensitivity to buried interfaces. Interestingly, the magnitude of the SPV signal is seen to increase with increasing annealing time (in air, at 200 °C), in agreement with the increase in overall solar cell efficiency with such annealing.

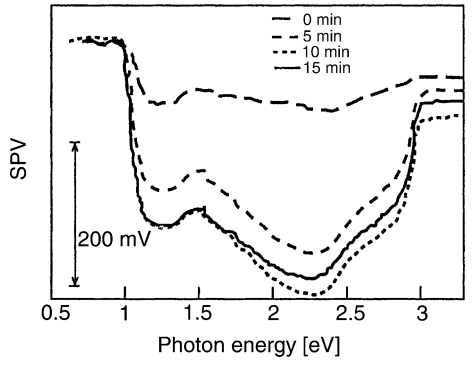

Figure 5 SPV spectra of ZnO:Al/ZnO/CdS/CIGS structures for various annealing times, in air, at 200 °C. Adapted from Gal D, Beier J, Moons E, *et al.* (1995) Band diagram and band line-up of the polycrystalline Cds/Cu(In,Ga)se_2 heterojunction and its response to air annealing. *AIP Conference Proceedings* 353: 453. Reproduced by permission of the American Institute of Physics.

Another feature of growing importance in SPS is that it allows for the characterization of quantum wells and other low-dimensional heterostructures. An illustrative example of the SPS of a multiple-quantum-well (MQW) GaAs/AlGaAs structure is shown in Figure 6a. The spectral knees at ~1.4 eV and 1.78 eV correspond to the onset of band-to-band absorption in the GaAs epilayer and the AlGaAs cap layer, respectively. In between these two knees, the shape of the SPV spectrum resembles typical absorption spectra of MQW structures and the observed MQW-related maxima agree well with calculated energy values of the hole level-electron level transitions denoted as 1HH-1E and 2HH-2E transitions. Note that before etching, a nonnegligible sub-bandgap SPV signal was apparent at photon energies below 1.38 eV, indicating the presence of optically active gap states. Since no such signal was observed after etching, these states were located at the external AlGaAs surface and were not associated with the MQW region. Moreover, the SPV spectrum in the MQW absorption energy range has not changed at all (other than undergoing a uniform shift) after etching, showing that the signal SPV in the MQW absorption range is not interfered by surface effects. Thus, all allowed hole–electron transitions have been resolved, at room temperature.

As SPV analyses of multilayer structures offer the possibility of performing contactless and nondestructive electrical and optical characterization of buried interfaces, they have found significant uses in the field of process monitoring and quality control of actual device structures. This is because the possibility of assessing the quality of a layered structure before any actual device processing takes place presents an opportunity for significant savings in time and money. Recent applications include the identification of defective batches and prediction of ultimate performance of solar cells and x-ray detectors, the prediction of energy levels and lasing wavelength in modern laser heterostructures, the assessment of bandgap narrowing and ultimate gain of heterojunction bipolar transistors, and the

characterization of the electronic structure of high electron mobility transistors and vertical cavity surface emitting lasers.

As an example of such studies, consider the recent characterization of an In-GaAs/GaAs/AlGaAs vertical-cavity surface-emitting laser, shown in Figure 6b. It is readily observed that SPS resolves both the gain providing 1C-1H transition and the lasing-wavelength-related cavity mode, as well as a rich oscillatory structure above ~1.37 eV due to interference effects from the distributed Bragg reflector stacks. The measured SPV spectrum is also in very good agreement with the calculated dependence of the photo-excited carrier density on photon energy, also shown in Figure 6b. In fact, SPS is the first contact-less technique to resolve all of these features in one measurement, and it also allows for a temperature-resolved determination of these quantities.

Summary

SPS features a theory that is relatively straightforward (at least at the qualitative level), and offers typical experimental setups that make the method contactless, nondestructive, ambient insensitive, and capable of any lateral resolution. It can provide a detailed picture of the electronic structure at surfaces, interfaces, heterojunctions, and even complicated multilayer structures. The wide range of SPS applicability also makes it easy to compare and link changes in electronic structure to changes in chemical/physical properties on the one hand, and electrical/optical device properties and performance on the other.

Bright Spatial Solitons

C Conti and G Assanto, University 'Roma Tre', Rome, Italy

Introduction

Optical spatial solitons, once considered an exotic and rather abstract concept belonging to the realm of mathematics or mathematical physics, nowadays are pursued both experimentally and theoretically in terms of their rich dynamics and variegated features, with important perspectives in applications to signal processing and switching, routing, filtering and – generally – light-by-light controlling. In an intuitive description of a bright spatial soliton, a self-focusing response balances natural diffraction of a light beam, allowing for its invariant propagation in transverse size and intensity. Spatial solitons can be regarded as the stationary or time-independent self-guided 'eigenwaves' of Maxwell equations in a material system with a nonlinear optical response. Basically, 'bright' spatial solitons (we will not address 'dark' cases here, i.e., a dip on an illuminated background) bear the same relationship to nonlinear optics in space as temporal, or fiber, solitons do in time. While both temporal and spatial solitons are special cases of light localization in the $(3 + 1)$ dimensions (light bullets) encompassing time and two transverse coordinates in space in addition to propagation; the spatial case requires particular attention compared to the fiber inasmuch as, in general, two transverse coordinates (2D) complement the direction of propagation. In other words, the scenario is potentially one-dimension richer than for 'standard' temporal solitons, where light confinement, i.e., the effect of the nonlinearity, takes place along a single coordinate. In this respect, the latter case finds a direct counterpart with spatial solitons in planar waveguides, i.e., $(1 + 1)$D solitons, where light confinement occurs linearly in one spatial dimension, providing group-velocity dispersion in time is replaced by beam diffraction in space, respectively.

When both transverse dimensions are involved, i.e. when a light beam propagates in bulk, in the simplest case of Kerr self-focusing, the nonlinearity can become overcritical and cause filamentation and catastrophic collapse. Additional mechanisms (such as saturation, nonlocality, or higher-order effects) or inherently different nonlinear responses (parametric or molecular), need therefore to be involved in the description of spatial solitons. In several instances, the mathematics differs from the nonlinear Schrödinger equation originally invoked to define a 1D bright optical soliton, leading to nonintegrable systems and

to a wider class of solutions, called solitary waves. Since solitary waves constitute the vast majority of the observed spatial light-localization phenomena, we will refer to spatial solitons even in those cases when their model is nonintegrable, defining them as non-diffracting beams in a self-focusing material. While retaining the distinction between 1D and 2D cases, in the following sections we will discuss bright spatial solitons and their features, grouping them on the basis of the underlying nonlinear mechanism and corresponding model, trying to provide a direct link with experimental observations. In doing so, we will leave out discussions on dark solitons and modulationally unstable phenomena, as well as more involved subjects ranging from higher-order to vector, vortex, photonic-crystal, and incoherent spatial solitons.

The General Model of Bright Spatial Solitons

Assuming the paraxial approximation to be valid, the general structure of the evolution equations which lead to spatial solitons propagating along z takes the so-called Foch–Leontovich form:

$$2ik\frac{\partial A}{\partial z} + \nabla_\perp^2 A = -2k^2\frac{\Delta n}{n_0}A \qquad [1]$$

where A is the complex amplitude of the linearly polarized electric field, $k = \omega/c = 2\pi n_0/\lambda$, with λ the wavelength, $\omega = 2\pi\nu$ the pulsation, n_0 the bulk refractive index, and $\Delta n(\mathbf{r})$ the index change induced by the nonlinear effect. In anisotropic materials, both n_0 and Δn may depend on the polarization of the envelope A. The latter is normalized such that the optical intensity is $I = |A|^2$. Hence the whole optical field is

$$E_{\text{opt}} = \text{Re}\left[\sqrt{\frac{2Z_0}{n_0}}A\text{e}^{-\text{i}\omega t + \text{i}kz}\right] \qquad [2]$$

with Z_0 being the vacuum impedance.

Hereafter we will neglect material losses and assume $\Delta n(\mathbf{r})$ to be real-valued. In the simplest case it is a function of the field intensity I calculated in $\mathbf{r}$. Typical models are the Kerr medium with $\Delta n = n_2 I$, or the saturable Kerr with $\Delta n = n_2 I/(1 + I/I_s)$ and I_s a saturation value; they are particular cases of local nonlinear media defined by a relation of the type $F[\Delta n(\mathbf{r}), I(\mathbf{r})] = 0$, with F a 'well-behaved' function.

There is also the possibility that the refractive index modification depends on the electromagnetic perturbation (e.g. the intensity) in a finite region, as happens with nonlocal solitons. In the latter case, F needs to be substituted by an integro-differential system of equations, i.e., it represents a functional between $\Delta n(\mathbf{r})$ and $I(\mathbf{r})$.

Relevant exceptions to eqn [1] are spatial solitons due to a quadratic nonlinearity, where a system of two coupled equations must be taken into consideration, and a description in terms of a refractive index change only holds in an approximate, and by no means physical, sense. Quadratic solitons will be discussed later. Here, instead of embarking into a general classification, we will describe the relationships to some representative cases. In this simple framework, spatial solitons are defined as solutions of the type $A = a\exp(\text{i}\beta z)$, with a real-valued and satisfying the equation:

$$\frac{1}{2k^2}\nabla_\perp^2 a + \frac{\Delta n(I)}{n_0}a = \frac{\beta}{k}a \qquad [3]$$

Equation [3] is the z-independent counterpart of eqn [1]. It has the form of the stationary Schrödinger equation (with a field-dependent Hamiltonian operator), where the kinetic energy and the potential are given by the diffraction term and by the nonlinear correction to the refractive index, respectively. Its solutions correspond to solutions of eqn [1] due to the balance between diffraction and nonlinearity. β is the nonlinear correction to the dispersion relation $k = n_0\omega/c$, i.e., it yields the resulting longitudinal wavevector $K = k + \beta$. Solitary solutions are often classified in terms of their dimensionality. Solutions of eqn [3], which depend on either 1 or 2 transverse coordinates, define 1D or 2D solitons, respectively. 1D solitons refer to situations in which a bulk nonlinear medium is illuminated with a highly elliptic beam (such that the diffraction along a transversal dimension, denoted by y, is negligible), or a planar waveguide is excited with a linear mode fixing the transverse profile in one of the dimensions (denoted by y). The nonlinear dynamics and the corresponding steady-state solutions are then described by eqns [1] and [3], with $\partial_y = 0$.

Spatial Solitons in Kerr Media

1D Kerr Spatial Solitons and the Nonlinear Schrödinger Equation

The simplest example of a spatial soliton is an optical beam diffracting in one transverse dimension in the presence of the so-called Kerr effect, i.e., a refractive index that increases linearly with the local intensity I:

$$n = n_0 + n_2 I \qquad [4]$$

where $n_2(>0)$ is measured in $m^2\ W^{-1}$ and has typical values of 10^{-20} for silica and 10^{-17} for semiconductors at photon energies below half-bandgap, i.e., leaving aside two photon absorption and higher-order effects. For 1D Kerr spatial solitons, eqn [1] becomes

$$2ik\frac{\partial A}{\partial z} + \frac{\partial^2 A}{\partial x^2} = -2k^2\frac{n_2}{n_0}|A|^2 A \qquad [5]$$

Equation [5] is known as the nonlinear Schrödinger equation (NLS), and is the basic model in describing temporal soliton, i.e., nondispersing pulses propagating in optical fibers, provided the variable x is intended as the temporal coordinate. The importance of eqn [5] is due to several remarkable, in some sense unique, mathematical properties, and to the fact that it can be considered a fundamental model for diverse nonlinear phenomena. This circumstance is often referred to as the 'universality of the NLS'.

In the framework of optical spatial solitons, the NLS relevance is moderated by the fact that most experimentally explored environments involve processes significantly more complicated than the Kerr effect. Nevertheless, it settles the basic principles and constitutes a reference point in optical soliton assessment.

Trying to gain some physical insight, the starting point is the beam spreading when $n_2 = 0$ in eqn [5], i.e., the linear regime corresponding to low intensities. The diffraction is inherent to the spectrum of plane waves in a finite beam (along x). To underline the role of the nonlinear response, one can consider the NLS without the diffraction term (the second derivative with respect to x), obtaining:

$$A(x,z) = \sqrt{I(x)}\,\exp\left[\mathrm{i}k\frac{n_2}{n_0}I(x)z\right] \qquad [6]$$

Equation [6] shows how the nonlinearity yields a phase-front curvature related to the sign of n_2: the medium is self-focusing (a converging beam) for $n_2 > 0$ or self-defocusing (a diverging beam) for $n_2 < 0$ (see **Figure 1**). In the absence of diffraction, i.e., for a plane wave, the Kerr effect modifies the field phase by increasing ($n_2 > 0$) or decreasing ($n_2 < 0$) the local refractive index (and hence the effective optical path) proportional to the intensity. For a beam of finite transverse extent, nonlinearity and diffraction act together. In a self-focusing medium, the concave phase-front due to diffraction can be balanced by the nonlinearity, and the natural tendency of a beam to spread can therefore be compensated. For this to happen, the length-scales associated to the diffraction, i.e., the Rayleigh range $L_R = kw_0^2$, and the Kerr effect must be comparable. A characteristic length $L_N = n_0/(kn_2I_0)$, over which the nonlinear phase shift equals 1, can be associated

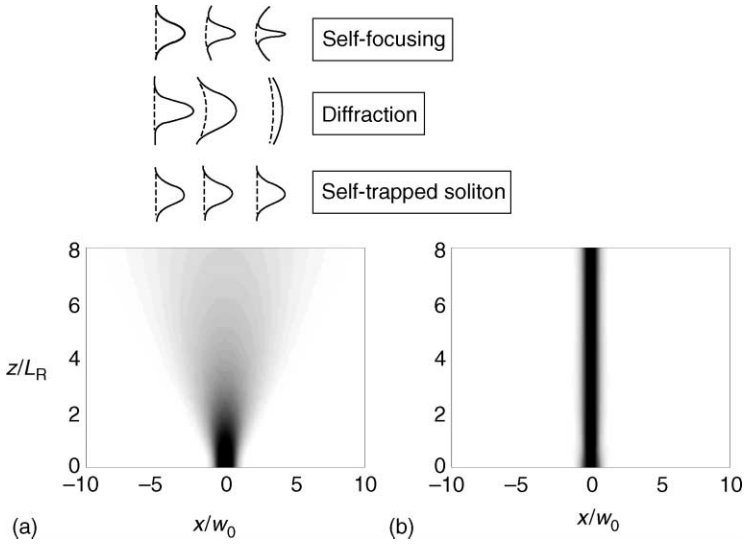

Figure 1 Kerr spatial solitons. Top: sketch of the mechanism leading to Kerr soliton formation. In the absence of diffraction, self-focusing of a Gaussian beam provides a converging phase-front (dashed lines). Conversely, diffraction by itself causes beam divergence. When these two effects act jointly, they can balance each other and soliton generation can be observed, with a flat phase-front. (Adapted with permission from Stegeman GI, Christodoulides DN and Segev M (2000) Optical spatial solitons: historical perspectives. *IEEE Journal of Selected Topics in Quantum Electronics* 6:1419–1426). Bottom: beam propagation method used to simulate the propagation of a one-dimensional Gaussian beam by integrating the nonlinear Schrödinger equation, for (a) low-power input, (b) input high enough to generate a self-trapped solitary wave. The transverse coordinate x is expressed in units of the beam waist, the propagation coordinate z in Rayleigh lengths.

to the nonlinearity, with I_0 the peak intensity across the beam profile. When the two lengths L_R and L_N are nearly equal, i.e., $w_0^2 I_0 \approx n_0/(k^2 n_2)$, the balance between the phase-front curvatures, due to diffraction and nonlinearity, yields a self-localized nondiffracting beam. Such a situation is described by the exact solutions of eqns [1] and [3], which takes the form:

$$A(x,z) = a(x)e^{i\beta z} \quad \text{with} \quad a(x) = \sqrt{I_0}\,\mathrm{sech}\left(x\sqrt{\frac{k^2 n_2}{n_0} I_0}\right) \qquad [7]$$

and $\beta = n_2 I_0/2n_0$ is determined by the peak intensity or, equivalently, by the power P_1 carried by the soliton per unit of transverse wavefront along y:

$$P_1 = \int_{-\infty}^{\infty} |A|^2\,dx = \sqrt{\frac{4n_0 I_0}{k^2 n_2}}$$

Note that the overall phase-front is flat, and the spatial extension in width yields $1/(n_2 k^2 I_0)^{1/2}$, as anticipated. The relationship between the soliton width – which determines the strength of diffraction – and the intensity – responsible for the nonlinear phase shift – is known as the existence curve, and is characteristic of the specific nonlinear mechanism.

Equation [7] is the fundamental soliton of the NLS and the paradigmatic 1D spatial soliton. Its sech shape specifically results from the type of nonlinearity; as discussed below, other effects (including parametric generation) can yield different profiles.

Figure 1 shows the simulation of a 1D Kerr soliton generated from a Gaussian input. Self-trapping is attained when the peak intensity or, equivalently, the power, reaches a threshold value depending on experimental details, the size of the nonlinear response, and the beam profile.

Figure 2 shows experimental results on the formation of a 1D Kerr soliton in a semiconductor (AlGaAs, $n_0 \approx 3.5$) waveguide. At low power (center panel) the output beam exhibits diffraction, whereas the soliton (bottom) reproduces the input beam profile (top panel) at the end facet of the sample. These results were obtained at $\lambda = 1.55$ μm, using pulsed laser beams, with temporal pulse durations of about 1 ps and peak powers of about 500 W; the generated 1D solitons had waists of tens of microns.

In a physically intuitive sense, self-trapping is due to the refractive index increase across the beam profile. Such an increase gives rise to a graded index optical waveguide able to confine all the plane wave components with angles of propagation within the numerical aperture of the input beam. Large spatial-frequency components k_x cannot be trapped and are emitted as radiation during soliton formation. It is possible to experimentally verify that this self-induced waveguide is also able to guide a weak probe uncorrelated to the soliton, provided it is above the cutoff for dielectric confinement. The use of spatial solitons for intensity-controlled or all-optical lightwave circuitry can therefore be envisaged. The first experiments on optical 1D Kerr spatial solitons date back to 1985, and were performed in carbon disulfide. Since then, 1D Kerr spatial solitons have been reported in glasses, semiconductors, and organic materials.

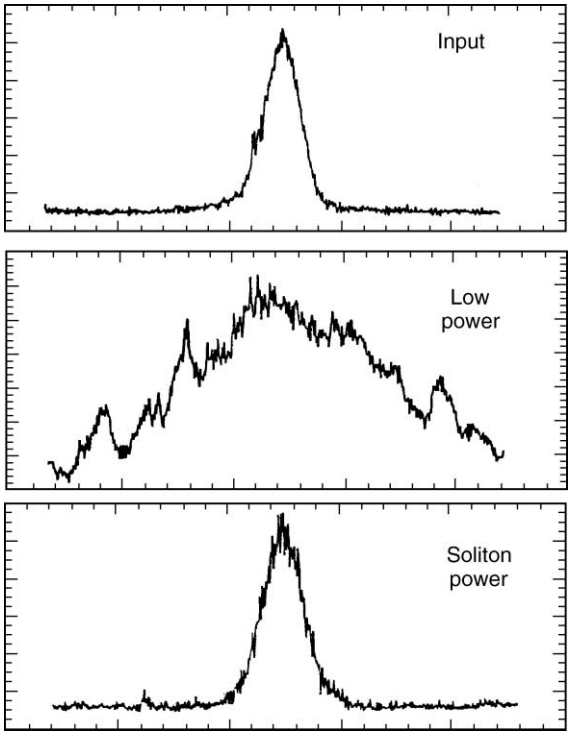

Figure 2 1D Kerr soliton in a planar AlGaAs waveguide. Transverse beam profiles at the input (top) and output facets of a planar waveguide in AlGaAs, at low (center) and high (bottom) power, showing diffraction and soliton formation, respectively. Kerr Spatial Solitons in Two Transverse Dimensions: Saturable and Nonlocal Media

When the dynamics of the optical beam encompasses two transverse dimensions, the idealized discussion above no longer applies. As long as the medium is described by the simple Kerr law (eqn [4]), 2D propagation does not admit stable self-trapped

stationary beams. Because of this, two alternatives are available: (i) the beam diffracts; or (ii) the beam progressively self-focuses until it undergoes catastrophic collapse: in the absence of additional limiting phenomena, such as plasma formation or nonparaxial/vectorial coupling, its waist keeps shrinking with a corresponding unbound increase in peak intensity (beam power is conserved). Which regime actually applies, depends on whether the excitation is lower or higher than a self-focusing critical power $P_c = (0.61\lambda)^2/8n_0n_2$. The latter corresponds to a diffraction-driven divergence equal to the critical angle for total internal reflection in the induced waveguide. The self-focusing instability, first predicted by Kelly in 1965, is related to the so-called Derrick's theorem: particularly related to spatial solitons in a positive ($n_2 > 0$) Kerr medium, it states that the equilibrium between diffraction and nonlinearity in 2D is unstable.

The situation is markedly different when saturation is present: self-focusing arrests at the maximum value of the nonlinear refractive index increase, and stable self-trapped beams are allowed. The simplest model for a saturating nonlinearity yields the following stationary-state equation:

$$\frac{1}{2k^2}\nabla_\perp^2 a + \frac{n_2}{n_0}\frac{I}{1+I/I_s}a = \frac{\beta}{k}a \qquad [8]$$

Its solutions, while retaining a bell-shaped profile, depart from the purely Kerr model corresponding to $I_s \to \infty$, and can only be obtained numerically.

Gases, and specifically sodium vapors, were the first media in which spatial solitons of a saturable Kerr-like nonlinearity were observed in 1974. Historically, these were the first 2D optical spatial solitons.

Most recent developments on optical spatial solitons involve more complicated environments and nonlinear responses. In the next sections we will consider those most investigated experimentally: photorefractive solitons, nonlocal solitons in liquid crystals and parametric solitons.

Spatial Solitons in Photorefractive Media

In recent years, research on spatial optical solitons in photorefractives has been among the most active. Self-trapping in photorefractive materials was first predicted in 1992 and observed in 1993. However, a clear assessment of this result came with the demonstration of the so-called steady-state screening photorefractive solitons in 1994.

The principle underlying the photorefractive response can be described as a feedback mechanism relating to the optical induction of a static electric field **E**. In specific materials, such as semiconductors or ferroelectrics, a light beam generates free charges which diffuse and drift under an externally applied voltage. Owing to free carriers and donor/acceptor sites, the resulting net spatial charge produces a static electric field which, in turn, modifies the refractive index n_0 via the electro-optic effect, phenomenologically described by

$$\Delta n_{ij} = -\frac{1}{2}n_0^3 r_{ijk}E_k - \frac{1}{2}n_0^3\varepsilon_0^2(\varepsilon_r - 1)^2 g_{ijkl}E_kE_l \qquad [9]$$

Equation [9] is a series expansion of the index change in powers of the static electric field: all terms are present if the medium is noncentrosymmetric, otherwise only even-powered terms need be included. In essence, eqn [9] entails the feedback mediated by the static electric field on the optical wave.

The feedback leads to stable solutions under appropriate conditions. These are steady-state solitons if the inhomogeneous light-induced index change makes a suitable waveguide for the beam. The three main types of such self-localized beams are screening, photovoltaic, and centrosymmetric photorefractive solitons. Boundary conditions determine the induced static field to be inserted in eqn [9] and in the propagation eqn [1]. In the simplest cases we consider, the light-wave is linearly polarized and the tensorial nature of the index perturbation in eqn [9] can be neglected.

The equations encompassing most of the physics of the photorefractive effect constitute the Kukhtarev model and can be shown as:

$$\begin{aligned} &s(I + I_b + I_{dark})(N_d - N_d^i) - \gamma_r \rho N_d^i = 0 \\ &\nabla\cdot\mathbf{J} = \nabla\cdot[q\mu\rho\mathbf{E} + k_B T\mu\nabla\rho + \beta_{ph}(N_d - N_d^i)I\mathbf{c}_{opt}] = 0 \\ &\nabla\cdot\mathbf{E} + \frac{q}{\varepsilon_S}(\rho + N_A - N_d^i) = 0 \end{aligned} \qquad [10]$$

The relevant quantities in eqns [10] are: the current density **J**; the free charges (electrons) density ρ; the density of ionized (total) donors N_d^i (N_d), the density of negatively charged sites N_A, the photo-ionization cross-section s, the background density I_b (due to background laser light), the dark irradiance I_{dark} (sI_{dark} is the dark generation rate, typically $I_b \gg I_{dark}$), the recombination rate γ_r, the electron mobility μ, the low frequency dielectric constant $\varepsilon_S = \varepsilon_0\varepsilon_r$, the Boltzmann constant k_B, the versor $\mathbf{c}_{opt}$ of the optic axis, and the temperature T. In the second of eqn [10], the pertinent element β_{ph} of the photovoltaic tensor needs be taken into account only for the photovoltaic solitons described below. The above must be completed by boundary conditions for the bias V – the line integral of

E – and the geometry of the metal contacts. Typically, $N_d \approx 10^{18}$ cm$^{-3} \gg N_a$, $I_{dark} \approx 10^{-3}$–10^{-6} W/cm^2, $I_b \approx 10$ W/cm^2, $\varepsilon_r \approx 10^3$ and solitons are observed in the visible.

Equations [10] determine the field **E** in terms of the optical intensity I in steady-state, and **E** is inserted in eqn [9] to yield the optically induced index change. A major signature of photorefractive solitons is the cumulative process they rely on: the space-charge field **E** builds up in time along with the distribution of carriers, until equilibrium is reached. Hence the phenomenon does not require high optical intensities but, conversely, a sufficiently long time (of the order of minutes or hours). Photorefractive solitons are typically observed at modest excitations, as low as a few microwatts, with typical waists of tens of microns.

Screening and Photovoltaic Solitons

When an externally applied bias lowers the refractive index of a crystal through its electro-optic response, a light beam can screen this effect, defining a self-waveguide supporting a spatial soliton. In a noncentrosymmetric photorefractive, the beam raises the conductivity in the illuminated region, locally lowering the voltage drop compared to dark regions. The induced space-charge screens the applied static field, and it may bring the refractive index back to its unbiased value. This can be seen as a voltage divider formed by a small optically controlled resistance and two large ones corresponding to the dark regions. The resulting solitary waves are called screening photorefractive solitons. For them to be stable (in time), additional illumination of intensity I_b at the same wavelength is required on the crystal in order to increase the conductivity of the (dark) regions surrounding the soliton. The charge accumulation in the beam-tails would otherwise flatten the induced index distribution and destroy the soliton.

The simplest description of screening solitons is provided by the saturating relationship between the electric field E and the light intensity I:

$$E = -\frac{V}{L}\frac{1}{1 + I/I_b} \qquad [11]$$

to be used in eqn [9] to get the index perturbation via the electro-optic effect. L is the width across which the voltage is applied. Since the quadratic term in eqn [9] (weighed by the tensor g_{ijkl}) can be neglected in noncentrosymmetric crystals:

$$\Delta n \approx -\frac{1}{2} n_0^3 r_{eff} E \qquad [12]$$

where r_{eff} is the relevant component of the electro-optics tensor; typically $n_0 \approx 2$, $r_{eff} \approx$ tens or hundreds of pm/V, and the overall index perturbation is of the order of 10^{-4}–10^{-3}, with $V/L \approx 10^3$ V/cm. This description applies to 1D solitons; for 2D solitons, sometimes referred to as 'needle' solitons, the whole set of constitutive equations must be solved numerically. Nevertheless, in most cases the saturating model, even if not rigorous, describes well solitons and related phenomena both theoretically and experimentally, especially when nonlocal effects can be ignored.

Figure 3 shows the propagation of a 2D spatial screening soliton (top) compared to the linear case (bottom). The diffractive regime is realized by artificially 'turning off' the nonlinearity acting on the applied voltage (when $V = 0$ in eqn [11] then $\Delta n = 0$, corresponding to no induced perturbation).

Another class of photorefractive spatial solitary waves is that of photovoltaic solitons. In this case the electric field in the crystal has an additional component through the photovoltaic effect, the latter being relevant in materials such as $LiNbO_3$. To sustain bright solitons the index perturbation due to the photovoltaic current, which induces the space-charge field, must be positive. This is the case for Cu:KNSBN, where 2D photovoltaic solitons were first observed.

The space-charge field, due to the photovoltaic effect, can be derived from the Kukhtarev model:

$$E = -E_{ph}\frac{I/I_b}{1 + I/I_b} \qquad [13]$$

with E_{ph} is a constant depending on the material ($E_{ph} \approx 10^3$ V/cm) and I_b is the dark-irradiance controlled by the background laser light. Typical

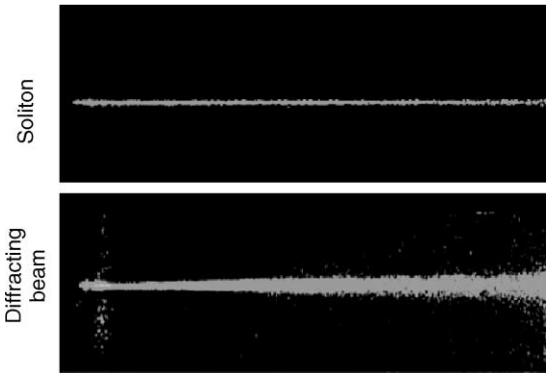

Figure 3 2D photorefractive soliton. Top view photograph of a 10 mm wide spatial soliton propagating in strontium barium niobate (top), and for comparison, the same beam diffracting when the nonlinearity if 'turned off' (bottom). (Adapted with permission from Stegeman GI, Christodoulides DN and Segev M (2000) Optical spatial solitons: historical perspectives. *IEEE Journal of Selected Topics in Quantum Electronics* 6: 1419–1426).

geometries account for the tensorial nature of the effect, and are arranged to make I_b of the same magnitude of the beam intensity I. If $E_{ph} > 0$, as in Cu:KNSBN, eqn [13] in eqn [12] shows that a positive index change of the saturating type can be induced and support bright solitons. This model is successfully used for both 1D and 2D bright photovoltaic spatial solitons.

Photorefractive Solitons in Centrosymmetric Media

Most experiments on screening solitons were performed in ferroelectric noncentrosymmetric crystals. When brought above the Curie temperature T_c, such materials exhibit a phase-transition to a centrosymmetric paraelectric state. Crystals such as Potassium Lithium Tantalate Niobate have room-temperature phase-transitions, conveniently enabling experimental investigations. In paraelectrics, the second-order electro-optic tensor r_{ijk} is zero because of symmetry, but the photorefractive effect is still available through the third-order coefficient g_{ijkl} in eqn [9]. By properly choosing the orientation, eqn [12] can then be replaced by

$$\Delta n = \frac{1}{2} n_0^3 \varepsilon_0^2 (\varepsilon_r - 1)^2 g_{eff} E^2 \qquad [14]$$

Operation near T_c greatly enhances the relevant electro-optic coefficient $g_{eff} > 0$ ($g_{eff} \approx 0.1\ m^4\ C^{-2}$), making the observation of photorefractive screening solitons possible. Using eqn [11] in eqn [14] the model is saturating and works for both 1D and 2D bright solitons.

Thanks to the low powers involved and a mature crystal technology, the photorefractive effect and related soliton phenomena have contributed several impressive results in optical morphology of nonlinear light propagation, including incoherent and white light excitations.

Spatial Solitons in Nonlocal Media, Liquid Crystalline Media

A link, such as the Kerr law (eqn [4]), between the index perturbation and the optical intensity is 'local', because Δn at a given point (x, y, z) only depends on the intensity at the same location. Otherwise the medium is said to be 'nonlocal', e.g., one of those described by the general Kukhtarev model (eqn [10]) although, sometimes well approximated by eqns [11] or [13].

There are various mechanisms yielding nonlocality, mainly through spatial diffusion of the index perturbation far from the excitation. Remarkable nonlocal effects are expected when the spatial features of the beam, e.g., its waist, are significantly smaller than those of the induced polarization.

One of the most important effects of nonlocality is the stabilization against the catastrophic self-focusing in 2D, as experimentally investigated by Suter and Blasberg in 1992. Evidence of a highly nonlocal behavior has been very recently reported in liquid crystals, where the nonlinearity can be thermal or re-orientational. In the former case the index perturbation is much wider than the beam waist due to thermal diffusion associated to (absorption mediated) heat transfer. In the latter case the elastic properties of the medium produce a widening of the self-waveguide far from the beam axis. In nematic liquid crystal (NLC), the re-orientational response stems from the optically induced tilt of the elongated molecules towards the linearly polarized field versor. The light forced re-orientation increases the refractive index, thus creating the self-guiding conditions for spatial solitons. However, since in the nematic phase the molecules are linked together in a wide-scale order, the region (kernel) affected by this process is determined by the elastic properties of the medium and can extend to tens of microns.

An effective approach to describe spatial solitons in a highly nonlocal medium (where the kernel is much larger than the beam) postulates that the punctual relationship between Δn and I is replaced by a link between Δn and the beam power P. In such a way the transverse integral of the intensity is fully embedded in the index perturbation.

Assuming $n = n(P, r)$ with the beam mainly subject to the refractive perturbation near its axis, one can write:

$$n^2(r, P) = n_0^2(P) - r^2 \gamma(P) \qquad [15]$$

with $n_0^2(P) \cong n_0^2$ the on-axis value. $\gamma(P)$ depends on the specific geometry and determines the wavefront convexity at the origin. The overall profile is basically determined by the constitutive relationships of the medium. The propagation equation can be shown as

$$2ik \frac{\partial A}{\partial z} + \nabla_\perp^2 A = \frac{k^2}{n_0^2} \gamma^2(P) r^2 A \qquad [16]$$

Equations like [16] also describe the transverse profile of a beam linearly propagating in optical fibers, as well as the quantum harmonic oscillator (interpreting z as time). The soliton is its nondiffracting solution, a particular stationary case of a more general Gaussian beam with waist variable in propagation.

For intensities:

$$I(z) = \frac{P}{\pi w^2(z)} e^{-r^2/w^2(z)} \qquad [17]$$

the spot-size obeys:

$$\frac{w^2(z)}{w_0^2} = 1 + \left[\frac{1}{k_0^2 w_0^4 \gamma^2(P)} - 1 \right] \sin^2 \left[\frac{n_0 z}{\gamma(P)} \right] \qquad [18]$$

Therefore, for a Gaussian excitation, the waist oscillates along z between the values w_0 – in general determined by the launch conditions – and $w_m = w_0 \gamma(P_S)/\gamma(P)$. P_s is the 'soliton power' for which $w_m = w_0$ and $k^{02} w_0^4 \gamma^2(P_S) = 1$, hence for $P < P_s$ or $P > P_s$ the beam pulsates cyclically with z (breathes). Such a dynamic balance between diffraction and nonlinearity stems from the spectral broadening associated to an increased beam shrinking: when the spectrum widens sufficiently, diffraction starts to prevail and the beam spreads again. This process repeats itself in propagation.

The stationary solution for $P = P_s$ corresponds to a point in the existence curve of waist versus power, i.e.:

$$k_0 w_0^2 \gamma(P_S) = 1 \qquad [19]$$

Such exact balance is critical, and experimentally observed solitary waves in highly nonlocal media appear as breathers.

Figure 4 displays the intensity profile of a soliton propagating in nematic liquid crystals, as acquired by a digital camera placed on the top of the cell and retrieving the scattered light (see Figure 5). The waist oscillation in the self-trapped beam and the dependence of the period on excitation are apparent.

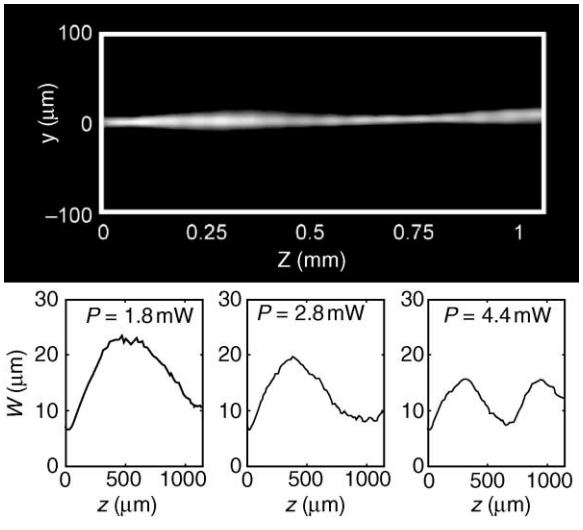

Figure 4 Nonlocal breather. (Top) top view photograph of a spatial soliton in NLC. Beam waist oscillations are apparent in propagation, as graphed (bottom panels) versus z for various excitations.

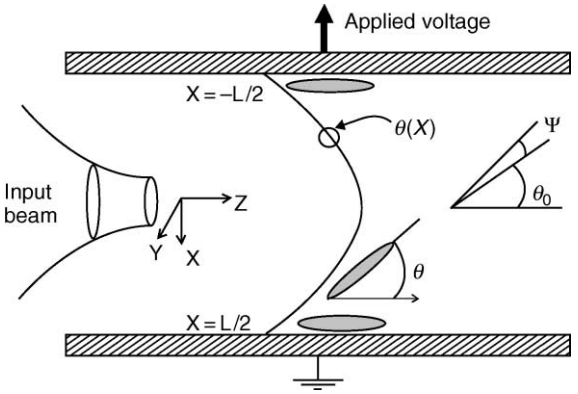

Figure 5 Sketch of a liquid crystal cell for the observation of nonlocal solitons. $\theta(x)$ is the orientation of the main axis of the ellipsoidal molecules, fixed by an external bias. The alignment is planar, with molecules parallel to the cell facets. The optical beam propagates in the center of the cell, where $\theta(x) = \theta_0$, and induces an additional re-orientation ψ. (Adapted from Conti C, Peccianti M and Assanto G (2003) Route to nonlocality and observation of accessible solitons. *Physics Review Letters* 91: 073901).

A specific highly nonlocal nonlinear system is formed by a linearly polarized beam in NLC with molecules pre-tilted (by an external electric or magnetic field) at $\theta_0 = \pi/4$ with respect to the input polarization. As sketched in Figure 5, the light wave induces an additional tilt Ψ. At the lowest order of approximation, the relevant set of equations can be shown as:

$$\begin{aligned} 2ik \frac{\partial A}{\partial z} + \nabla_\perp^2 A &= -k^2 \frac{n_a^2}{n_0^2} \Psi A \\ K \nabla_\perp^2 \Psi - G\Psi + \frac{n_a^2}{2cn_0} |A|^2 &= 0 \end{aligned} \qquad [20]$$

with K the NLC elastic constant ($K \approx 10^{-11}$ N, for NLC of the E7 type), $n_0 \approx 1.5$, n_a^2 the optical anisotropy ($n_a \approx 1$), i.e., the difference between relative permittivities along the two principal axes, G a constant determined by the specific geometry of the NLC cell and the pre-tilt angle θ_0. Since, for $K = 0$, eqn [20] represents a Kerr medium, it can be considered one of the simplest nonlocal generalizations of local models for spatial solitons. The length $R_c = \sqrt{K/G}$ quantifies the diffusion of the index perturbation away from the beam axis, such that Ψ decays according to the modified Bessel function $K_0(r/R_c)$. Typically, $R_c \approx 20\ \mu$m and solitons are observed in the visible and near-infrared.

Solitary wave profiles are found with the ansatz $A = a\exp(\mathrm{i}\beta z)$, obtaining:

$$\begin{aligned} \frac{\nabla_\perp^2 a}{2k^2} + \frac{n_a^2}{2n_0^2}\Psi a &= \frac{\beta}{k}a \\ R_c^2\nabla_\perp^2\Psi + \frac{R_c^2 n_a^2}{2Kcn_0}a^2 &= \Psi \end{aligned} \qquad [21]$$

No analytical solutions of eqns [21] are known in 2D, hence the profiles have to be derived numerically. Conversely, it can be shown that 1D sech^2 solutions exist (see next section on parametric solitons). From eqn [21], the whole family can be parameterized by a dimensionless $\alpha = 1/(2k\beta R_c^2)$. Since $(1/2k\beta)^{1/2}$ measures the soliton waist (see eqn [7]), α relates the beam size and the extension of the induced perturbation. Small α solutions access the highly nonlocal regime, as shown in Figure 6, where the ratio R between the index perturbation and the soliton waist is graphed. The insets show sample profiles of a and ψ in two limits, respectively. On the other hand, when $K = 0$, $R_c = 0$, and $\alpha \to \infty$, the local limit yields an index perturbation comparable in size to the beam waist.

It is worth pointing out that a model such as eqn [16], also derived in the framework of plasma physics, predicts unconditionally stable self-trapped beams. Nonlocal solitons realize an energy minimum, thus preventing beam collapse such as in saturable (Kerr) media. The oscillations observed in experiments can be regarded as fluctuations around the lowest energy state.

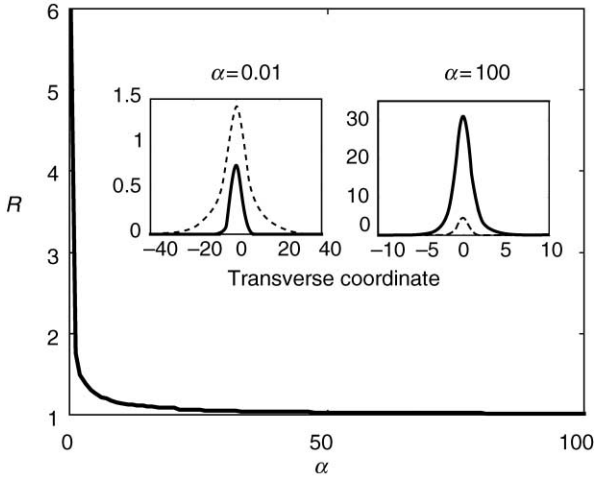

Figure 6 Spatial solitons versus nonlocality. Graph of the ratio R between the waist of the induced index perturbation in a nonlocal medium and the soliton waist versus parameter α. The insets show (in normalized units) soliton (solid line) and perturbation profiles (dashed line) for two different α, i.e., in the local ($\alpha = 100$) and highly nonlocal ($\alpha = 0.01$) regimes. (Adapted from Conti C, Peccianti M and Assanto G (2003) Route to nonlocality and observation of accessible solitons. *Physics Review Letters* 91: 073901).

Parametric Spatial Solitons in Quadratic Media

Solitons due to parametric processes, such as second-harmonic generation, belong to a different class with respect to previous sections. In fact, no refractive index modification can be physically associated to parametric effects. Parametric solitons are characterized by a power spectral density peaked around at least two carrier harmonic frequencies. It is the interaction between these components which provides the diffraction beating mechanism. Their existence was predicted in the early 1970s by Sukhorukov and Karamzin, while the first experimental evidence was reported in 1995.

The simplest process to address is second-harmonic generation (SHG): a fundamental frequency (FF) wave at ω interacts with a component at 2ω. The latter can be spontaneously generated in noncentrosymmetric crystals (e.g., $LiNbO_3$, $KNbO_3$, BBO, KTP, etc.) or externally seeded.

For plane waves, this process is ruled by:

$$\begin{aligned} \mathrm{i}\frac{\mathrm{d}A_1}{\mathrm{d}z} + \frac{\omega d_{\mathrm{eff}}}{c}A_1^* A_2\,\mathrm{e}^{-\mathrm{i}\Delta kz} &= 0 \\ \mathrm{i}\frac{\mathrm{d}A_2}{\mathrm{d}z} + \frac{\omega d_{\mathrm{eff}}}{c}A_1^2\,\mathrm{e}^{\mathrm{i}\Delta kz} &= 0 \end{aligned} \qquad [22]$$

with $\Delta k = k_1 - 2k_2 = 2\omega/c(n_1 - n_2)$ the phase mismatch, d_{eff} the nonlinear coefficient, n_2 and n_1 the indices at SH and FF, respectively, and

$$E_{\mathrm{opt}} = \mathrm{Re}\left[\sqrt{\frac{2Z_0}{n_1}}A_1\mathrm{e}^{-\mathrm{i}\omega t+\mathrm{i}k_1 z} + \sqrt{\frac{2Z_0}{n_2}}A_2\mathrm{e}^{-2\mathrm{i}\omega t+\mathrm{i}k_2 z}\right]$$

the overall electric field. d_{eff} relates to the quadratic susceptibility $d_{\mathrm{eff}}^{(2)}$ (measured in mV^{-1}) through to $d_{\mathrm{eff}} = d_{\mathrm{eff}}^{(2)}\sqrt{2Z_0}/(n_1\sqrt{n_2})$, and typically $d_{\mathrm{eff}} \approx 10^{-10}\,\mathrm{m}^2\,\mathrm{W}^{-1/2}$.

Equations [22] show that, in general, the harmonics with amplitudes A_1 and A_2 affect each other's phase and intensity during propagation. The solution with constant moduli, i.e.:

$$\begin{aligned} A_1 &= \sqrt{I_1}\exp\left[\mathrm{i}\frac{\omega}{c}\Delta n_1 z\right] \\ A_2 &= \sqrt{I_2}\exp\left[\mathrm{i}\frac{2\omega}{c}\Delta n_2 z\right] \end{aligned} \qquad [23]$$

with I_1 and I_2 the respective intensities, provides a 'pure' phase variation and 'apparent' index changes Δn_1 and Δn_2 on either wave. The latter satisfy:

$$\Delta n_1 = d_{\text{eff}}^2 \frac{I_2 - I_1/2}{n_1 - n_2}$$
$$\Delta n_2 = d_{\text{eff}}^2 \frac{I_1}{2I_2} \frac{I_2 - I_1/2}{n_1 - n_2} \qquad [24]$$

with the constraint (for plane waves to exist):

$$I_1 = 2I_2 - 2\frac{n_1 - n_2}{d_{\text{eff}}}\sqrt{I_2} \qquad [25]$$

Equations [24] encompass a great deal of the physics in self-trapping via SHG. When eqn [25] is satisfied (at least approximately), the effect of SHG is exclusively on the phase. Assuming eqn [24] is valid for (wide) beams, the propagation in the presence of diffraction can be described by two coupled equations of the type [1] with relevant perturbations (eqn [24]). This shows that the sign of the term $(2I_2 - I_1)/(n_1 - n_2)$ is crucial, because focusing at both harmonics ($\Delta n_{1,2} > 0$) requires $(2I_2 - I_1)/(n_1 - n_2) > 0$.

When just a fundamental frequency (ω) is launched, solitons are generated for $\Delta k > 0$: a small 2ω component is provided via SHG and $I_1 > 2I_2$. In fact, since SHG ($\omega + \omega = 2\omega$) is followed by difference frequency generation ($2\omega - \omega = \omega$, DFG), for any finite mismatch $\Delta k > 0$, a portion of the FF travels for a while at 2ω before it is back-converted: this is commonly named 'cascading' and, as a consequence, part of the FF undergoes a positive phase shift. The converse happens in the DFG + SHG process. Finally, if an SH beam with a small FF seed is input, solitons form for $\Delta k < 0$ being $2I_2 > I_1$. From a physical point of view, these mechanisms create the phase-front distortion required to counteract diffraction. Figure 7 is an artist's sketch on the formation of an SHG soliton.

Equations [24] are approximately valid and rely on a plane-wave insight, but they point out the wealth of possibilities offered by three-wave interactions for light transverse localization via parametric processes. The full set of coupled equations describing parametric solitons from SHG differs from eqn [1]:

$$\mathrm{i}\frac{\mathrm{d}A_1}{\mathrm{d}z} + \frac{1}{2k_0 n_1}\nabla_\perp^2 A_1 + \frac{\omega d_{\text{eff}}}{c} A_1^* A_2 \mathrm{e}^{-\mathrm{i}\Delta k z} = 0$$
$$\mathrm{i}\frac{\mathrm{d}A_2}{\mathrm{d}z} + \frac{1}{4k_0 n_2}\nabla_\perp^2 A_2 + \frac{\omega d_{\text{eff}}}{c} A_1^2 \mathrm{e}^{\mathrm{i}\Delta k z} = 0 \qquad [26]$$

as it includes diffraction terms added to eqn [22].

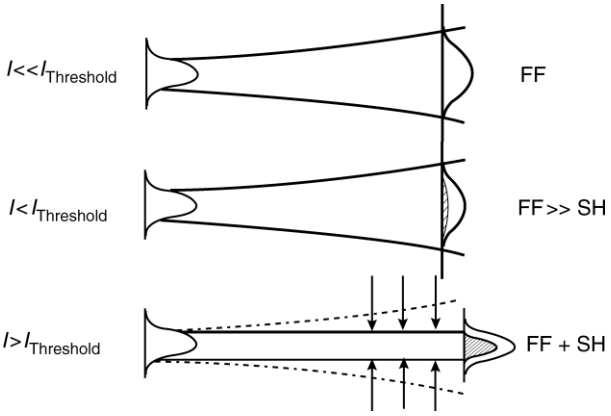

Figure 7 Parametric solitons via SHG. Intuitive description of soliton formation with an FF Gaussian input. At low powers (top) and for a small amount of generated SH (center) linear diffraction dominates. Above threshold parametric gain efficiently counteracts diffraction, originating a spatial soliton via quadratic cascading.

The self-trapped solutions are found as in eqn [23], with

$$A_1 = a_1(x, y)\exp(\mathrm{i}\beta z)$$
$$A_2 = a_2(x, y)\exp(\mathrm{i}\Delta k z)\exp(2\mathrm{i}\beta z), \quad \text{and} \qquad [27]$$
$$a_{1,2}(x, y) = \sqrt{I_{1,2}(x, y)}$$

These show that, even in the presence of diffraction, SHG can give rise to pure phase effect if the profiles satisfy:

$$\frac{1}{2k_0 n_1}\nabla_\perp^2 a_1 + \frac{\omega d_{\text{eff}}}{c} a_1 a_2 = \beta a_1$$
$$\frac{1}{8k_0 n_2}\nabla_\perp^2 a_2 + \frac{\omega d_{\text{eff}}}{2c} a_1^2 = \beta + \frac{\Delta k}{2} a_2 \qquad [28]$$

which are the space-dependent counterpart of eqn [25]. Again, β is a nonlinear contribution to the FF wavevector, and determines the corresponding correction $\beta_2 = 2\beta + \Delta k$ at SH. β is univocally determined by the power of the two harmonics in the solutions of eqn [28].

In the particular case:

$$\Delta k = \beta\frac{n_1 - 4n_2}{2n_2} \qquad [29]$$

1D parametric solitons exhibit profiles

$$a_1 = \sqrt{\frac{n_1}{n_2}}\frac{3c}{4\omega d_{\text{eff}}}\beta\,\mathrm{sech}\left(\sqrt{\frac{\beta k_0 n_1}{2}}x\right)^2$$
$$a_2 = \frac{3c}{4\omega d_{\text{eff}}}\beta\,\mathrm{sech}\left(\sqrt{\frac{\beta k_0 n_1}{2}}x\right)^2 \qquad [30]$$

and the powers per unit of transverse wavefront along y at the two components are:

$$P_1 = \int_{-\infty}^{\infty} a_1^2(x)\mathrm{d}x = \frac{n_1}{n_2}\frac{3\sqrt{2}c^2}{4\omega^2 d_{\mathrm{eff}}^2\sqrt{k_0 n_1}}\beta^{3/2}$$
$$P_2 = \int_{-\infty}^{\infty} a_2^2(x)\mathrm{d}x = \frac{3\sqrt{2}c^2}{4\omega^2 d_{\mathrm{eff}}^2\sqrt{k_0 n_1}}\beta^{3/2} \quad [31]$$

with the total soliton power $P_1 + P_2$, directly related to β.

Equation [29] implies that, for $n_1 > 4n_2$ and therefore $\Delta k > 0$, 1D parametric solitons exhibit the sech^2 profile. Otherwise, no analytical solutions are known even in 1D, and numerical techniques need to be employed. The same applies to 2D soliton profiles in all instances.

Notably, eqns [28] are essentially identical to eqns [21] for solitons in NLC. Therefore, Figure 4 provides the features of 2D parametric solitons as well, with 'a' replaced by 'a_1', and 'Ψ' by 'a_2'. For parametric solitons $\alpha = 4n_2(1 + \Delta k/2\beta)/n_1$, showing that at phase-matching ($n_2 = n_1$, $\Delta k = 0$) $\alpha = 4$, while large α's correspond to large Δk or small β's, e.g., low power and very wide solitons. The sech^2 profile for 1D solitons corresponds to $\alpha = 1$. 1D and 2D soliton solutions exist for any $\alpha > 0$.

The model for SHG solitons is more complicated than the previously discussed Kerr or saturable cases. The stability question can be formulated as the constrained-minimum problem of a specific functional, the Hamiltonian H. In general, for a given soliton power (the sum of the powers at the two harmonics) two branches exist for H. They correspond to two solitary solutions, differing in the ratio between the two powers. The solution with $P_2 > P_1$ corresponds to higher H, and is unstable via parametric amplification. When a harmonic field propagates in the presence of energy at a subharmonic (e.g., a small amount of FF), it tends to break up and transfer energy to it. Looking at Figure 4, this corresponds to small α's, only attainable when $\Delta k < 0$. As a result, quadratic solitons with a relevant SH content are unstable and thus, more difficult to observe.

The generation of a parametric soliton with a Gaussian input at FF, has a threshold (see Figure 7). This is because the input has to generate sufficient SH in order to produce and 'feel' the nonlinear phase-shift. A numerical simulation of eqn [26] shows the formation of a parametric spatial soliton, as displayed in Figure 8. As shown in (a), if only a small second-harmonic is generated by an FF excitation, diffraction dominates. Above threshold, as in (b), a stable self-trapped two-color beam is generated.

Two significant experimental results are reproduced in Figures 9 and 10. The photograph in Figure 10 shows a soliton propagating in periodically poled KTP (PPKTP) over five Rayleigh ranges, obtained by imaging the out-of-plane scattered light. Parametric solitons are typically observed with the FF in the near-infrared and the SH in the visible.

Figure 10 shows the output spots at FF and SH of a beam propagating in PPKTP for various FF excitations, until a soliton is generated (right end).

We close this section by observing that more general models must be considered to describe the whole physics of solitons in media with a quadratic

response. We mention, for example, the subtleties associated to anisotropy (walk-off), nondegenerate three wave interactions, additional Kerr and higher-order effects.

Conclusions

Bright spatial solitons are widespread, and have been reported in several materials using various wavelengths and geometries. The brief overview presented above was intended to introduce the variety of basic mechanisms underlying their generation and propagation, but could not even touch upon the wealth of additional properties and potential applications of individual and multiple spatial solitons, their interactions and collisional properties, their stability and their control with other linear and nonlinear light waves, as well as with additional nonoptical effects (temperature, voltage, acoustic, and magnetic fields, etc.). Fascinating phenomena involve bright spatial solitons and are the subject of current research. Among them we like to mention all-optical logic and signal readdressing, beam shaping and filtering, limiting, sub-wavelength spatial compression, and digital imaging. To learn more on the subject, we encourage the interested readers to look up the vast literature covering both fundamental and applied aspects of optical spatial solitons.

List of Units and Nomenclature

Angular frequency [s^{-1}]	ω
Beam waist [m]	w
Boltzmann constant [$J\,K^{-1}$]	k_B
Current density vector [$A\,m^{-2}$]	$\mathbf{J}$
Density of ionized donors [m^{-3}]	N_d^i
Dielectric constant of vacuum [$F\,m^{-1}$]	ε_0
Director angle perturbation [rad]	ψ
Director orientation angle [rad]	θ_0
Electric field amplitude, normalized [$W^{1/2}\,m^{-1}$]	a, A
Electric field amplitude, optical frequency [Vm^{-1}]	E_{opt}
Electric field vector, low frequency [$V\,m^{-1}$]	$\mathbf{E}$
Electron charge [C]	q
Electron density [m^{-3}]	ρ
Electron mobility [$m^2\,V^{-1}\,s^{-1}$]	μ
Electro-optic second-order tensor [$m\,V^{-1}$]	r, r_{ijk}

Electro-optic third-order tensor $[m^4\ C^{-2}]$	g_{eff}, g_{ijkl}
Element of the photovoltaic tensor $[C\ m^3\ J^{-1}]$	β_{ph}
Kerr nonlinear coefficient $[m^2 W^{-1}]$	n_2
Low frequency permittivity $[F\ m^{-1}]$	ε_S
Medium elastic constant [N]	K
Medium forcing constant $[N\ m^{-2}]$	G
Non local decay distance [m]	R_c
Nonlinear length [m]	L_N
Nonlinear wavevector correction $[m^{-1}]$	β, β_2
Optic axis versor	$\mathbf{c}_{\text{opt}}$
Optical background intensity $[Wm^{-2}]$	I_b
Optical dark intensity $[Wm^{-2}]$	I_{dark}
Optical index anisotropy	n_a
Optical intensity $[Wm^{-2}]$	I
Optical saturation intensity $[Wm^{-2}]$	I_S
Photo-ionization cross-section $[m^2\ J^{-1}]$	s
Photovoltaic index perturbation constant $[V\ m^{-1}]$	E_{ph}
Power [W]	P
Power per wavefront unit $[W\ m^{-1}]$	P_1, P_2
Propagation coordinate [m]	z
Rayleigh length [m]	L_R
Recombination rate $[m^3\ s^{-1}]$	γ_r
Refractive index	n
Refractive index perturbation	Δn
Relative dielectric constant	ε_r
Sample width [m]	L
Second order effective susceptibility $[m\ V^{-1}]$	$d^{(2)}_{\text{eff}}$
Second order nonlinear coefficient $[m\ W^{-1/2}]$	d_{eff}
Self-focusing power [W]	P_c
Soliton power [W]	P_S
Speed of light in vacuum $[ms^{-1}]$	c
Static dielectric constant $[F\ m^{-1}]$	ε_s
Temperature [K]	T
Total density of negatively charged sites $[m^{-3}]$	N_A
Total donor density $[m^{-3}]$	N_d
Transverse coordinates [m]	x, y, r
Transverse wave-vector $[m^{-1}]$	k_x
Vacuum impedance $[\Omega]$	Z_0
Wavelength [m]	$\lambda = 2\pi n/k = 2\pi/k_0$
Wavevector in medium $[m^{-1}]$	$k = n\omega/c$
Wavevector in vacuum $[m^{-1}]$	$k_0 = \omega/c$

Introduction

In the last few decades there has been considerable effort made in understanding energy-localization phenomena in many areas of physics. Optical fibers constitute excellent media where such phenomena are routinely observed by means of relatively simple experimental setups. A well-known example of those energy-localization phenomena is the optical soliton, which corresponds to a light pulse that can propagate in optical fibers over relatively long distance without experiencing significant degradations. From a fundamental point of view, the high stability of the optical soliton results from a delicate balance between the fiber chromatic dispersion and the nonlinear refractive (or Kerr) index. The idea of using optical solitons as information bits in high-speed communication systems was first proposed in 1973, and then demonstrated experimentally in 1980. After these discoveries, interest in optical soliton transmission started to increase. In an ideal fiber, optical solitons can be modeled approximately by the nonlinear Schrödinger equation, whose solutions are well known. In this article we present the main types of soliton behavior and the fundamental physical processes that are involved in soliton stability.

The Nonlinear Schrödinger Equation

In optical fibers, there are many nonlinear phenomena that are difficult to understand by direct analysis of the nonlinear polarization (e.g., the soliton effect) but that can be readily understood by use of the nonlinear Schrödinger equation (NLSE). Let us consider an optical pulse that propagates in the z-direction, in a dielectric Kerr medium such as an optical fiber, with frequency ω_0, wavenumber k_0, and an envelope $\mathcal{A}$:

$$E = \mathcal{A}\exp[\mathrm{i}(\mathbf{k}_0\cdot\mathbf{r} - \omega_0 t)] \qquad [1]$$

We assume that the wave envelope $\mathcal{A}$ varies slowly in time and space compared with the fast variations of the carrier wave ω_0. In this situation, the Fourier spectrum of the wave is restricted to frequencies and wavenumbers close to $\omega = \omega_0$ and $k = k_0$, respectively. Then, the wavenumber k can be expanded in a Taylor series around k_0, as follows:

$$k(\omega) = k_0 + \left(\frac{\partial k}{\partial \omega}\right)_{\omega_0}(\omega-\omega_0) + \frac{1}{2}\left(\frac{\partial^2 k}{\partial \omega^2}\right)_{\omega_0}(\omega-\omega_0)^2 + \left(\frac{\partial k}{\partial |\mathcal{A}|^2}\right)_{\mathcal{A}_0=0}|\mathcal{A}|^2 + \cdots \qquad [2]$$

The nonlinear term $Q = \left(\partial k/\partial|\mathcal{A}|^2\right)_{\mathcal{A}_0=0}$ arises from the optical Kerr effect, as $k = n\omega/c = k(\omega, |\mathcal{A}|^2)$.

Setting $K = k - k_0$, $\Omega = \omega - \omega_0$, $\beta_1 = (\partial k/\partial\omega)_{\omega_0}$ and $\beta_2 = \left(\partial^2 k/\partial\omega^2\right)_{\omega_0}$, one can rewrite eqn [2] as

$$K = \beta_1\Omega + \frac{1}{2}\beta_2\Omega^2 + Q|\mathcal{A}|^2 \qquad [3]$$

where β_1 is the inverse of the group velocity and β_2 is the group velocity dispersion (GVD) coefficient. Equation [3] represents the nonlinear dispersion relation for the envelope. Using a Fourier transform method in which K is replaced by a spatial operator $-\mathrm{i}\,\partial/\partial z$, and Ω by a temporal operator $\mathrm{i}\,\partial/\partial T$, one can apply eqn [3] on the envelope $\mathcal{A}$ to obtain the following equation:

$$\mathrm{i}\frac{\partial\mathcal{A}}{\partial z} + \mathrm{i}\beta_1\frac{\partial\mathcal{A}}{\partial T} - \frac{1}{2}\beta_2\frac{\partial^2\mathcal{A}}{\partial T^2} + Q|\mathcal{A}|^2\mathcal{A} = 0 \qquad [4]$$

In practice it is more convenient to make use of the quantity $A = (\alpha A_{\mathrm{eff}})^{1/2}\mathcal{A}$, for which $|A|^2$ represents the wave power. The parameter A_{eff} is the effective core area, which takes into account the variation of the light intensity across the transverse section of the fiber. The value of A_{eff} strongly depends on the mode distribution. Using a system of coordinates that moves at the group velocity v_{g}, i.e., replacing T by $t = T - z/v_{\mathrm{g}}$, eqn [4] reduces to the basic NLSE:

$$\mathrm{i}\frac{\partial A}{\partial z} - \frac{1}{2}\beta_2\frac{\partial^2 A}{\partial t^2} + \gamma|A|^2 A = 0 \qquad [5]$$

where γ is the nonlinear coefficient defined by $\gamma = Q/(\alpha A_{\mathrm{eff}}) = \omega_0 n_2/(cA_{\mathrm{eff}})$ and expressed in $\mathrm{W}^{-1}\mathrm{m}^{-1}$. This equation is formally analogous to the Schrödinger equation in quantum mechanics but with a nonlinear potential. Furthermore, in this basic NLSE, all higher-order terms that describe effects such as the fiber losses, third-order dispersion, or stimulated Raman scattering, are neglected. The NLSE for pulse propagation in optical fibers was

first derived in 1973 by Hasegawa and Tappert. It has also found applications in other areas of physics, such as in plasma physics, fluid dynamics and electrical transmission lines. From a fundamental point of view, the basic NLSE involves the combined effects of the group velocity dispersion (GVD) and self-phase modulation (SPM), which are described by the second and third terms in eqn [5], respectively. Each of these two effects is analyzed below.

Group Velocity Dispersion

The individual effect of the GVD on pulse propagation can be obtained by setting the nonlinear coefficient to zero ($\gamma = 0$). In this case, eqn [5] reduces to

$$\mathrm{i}\frac{\partial A}{\partial z} = \frac{1}{2}\beta_2 \frac{\partial^2 A}{\partial t^2} \qquad [6]$$

In the frequency domain, eqn [6] becomes

$$\mathrm{i}\frac{\partial \tilde{A}}{\partial z} = -\frac{1}{2}\beta_2 \omega^2 \tilde{A} \qquad [7]$$

where $\tilde{A}$ represents the Fourier transform of A. The solution of eqn [7] is given by

$$\tilde{A}(z,\omega) = \tilde{A}(0,\omega)\exp(\mathrm{i}\beta_2\omega^2 z/2) \qquad [8]$$

As eqn [8] shows, the GVD changes the phase of each spectral component of the pulse by an amount that depends on the propagated distance and the frequency of the spectral component. But this effect does not modify the power spectrum: $(|\tilde{A}(z,\omega)|^2 = |\tilde{A}(0,\omega)|^2)$. This phase change can modify the shape of the pulse envelope. For example, a Gaussian pulse with a width of δ_0 at $z = 0$, $A(z=0,t) = \exp\{(-t^2/(2\delta_0^2)\}$, will transform into

$$A(z,t) = [\delta_0^2/(\delta_0^2 - \mathrm{i}\beta_2 z)]^{1/2}\exp[-t^2/2(\delta_0^2 - \mathrm{i}\beta_2 z)] \qquad [9]$$

at a distance z. In other words, the pulse width increases from δ_0 to $\delta_0[1+(z/L_\mathrm{D})^2]^{1/2}$. The parameter $L_\mathrm{D} = \delta_0^2/|\beta_2|$ defines a dispersion length, that is, a length scale over which the dispersive effects become important. At $z = L_\mathrm{D}$ the Gaussian pulse broadens by a factor of $\sqrt{2}$. Thus, the GVD causes the spectral components of the pulse to move at different velocities, which broadens the pulse, as shown by Figure 1.

Another important effect of the GVD comes from the time dependence of the pulse phase, which one can easily obtain by rewriting eqn [9] as $A(z,t) = |A(z,t)|\exp[\mathrm{i}\phi(z,t)]$. It turns out that the GVD induces an instantaneous variation of the frequency across the pulse, called a frequency chirp. For the initially unchirped Gaussian pulse, the GVD induces a chirp given by

$$\delta\omega = -\frac{\partial\phi}{\partial t} = \frac{t\beta_2(z/L_\mathrm{D})}{|\beta_2|\delta_0^2[1+(z/L_\mathrm{D})^2]} \qquad [10]$$

As eqn [10] illustrates, the GVD-induced frequency chirp depends on the sign of β_2, and varies linearly across the pulse.

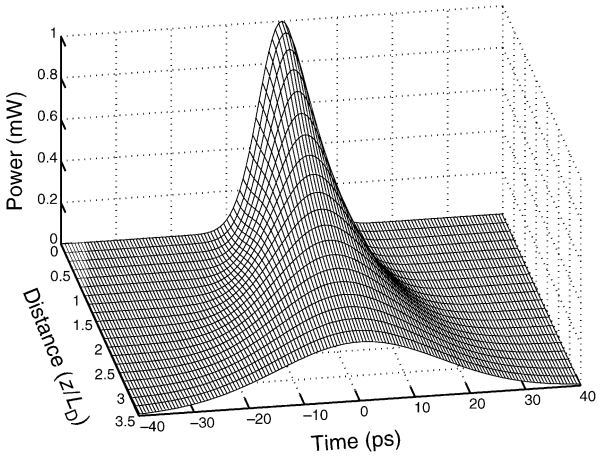

Figure 1 Temporal evolution of the power of a Gaussian pulse, as a function of the propagation distance. The simulation parameters are the following: input peak power $P_0 = 1$ mW, $\beta_2 = -20$ ps^2 km^{-1}, $\gamma = 3\times10^{-3}$ m^{-1} W^{-1} and $\delta_0 = 10$ ps. The dispersion length is $L_\mathrm{D} = 1.8$ km.

Self-Phase Modulation

Similarly to dispersion effects, nonlinear effects in optical fibers require a minimum propagation distance to develop significantly. The distance over which nonlinear effects become important is defined as the nonlinear length L_NL, given by $L_\mathrm{NL} = 1/(\gamma P_0)$, where P_0 is the peak power.

Let us consider the propagation of a light pulse in a fiber of length L, such that $L_\mathrm{NL} < L \ll L_\mathrm{D}$. In this particular case, the effects of dispersion can be neglected, and then the NLS equation becomes

$$\mathrm{i}\frac{\partial A}{\partial z} + \gamma|A|^2 A = 0 \qquad [11]$$

It results from this equation that $|A(z,t)|^2 = |A(z=0,t)|^2$. This means that the pulse shape remains unchanged during propagation. The solution of eqn [11] is given by

$$A(z,t) = A(0,t)\exp[\mathrm{i}\Phi_\mathrm{NL}(z,t)] \qquad [12]$$

where $\Phi_{NL}(z,t) = \gamma|A(0,t)|^2 z$. Thus, the Kerr effect causes the phase of the wave envelope to vary during the propagation. The nonlinear phase shift Φ_{NL} increases with the propagated distance z. The maximum phase shift Φ_{NL}^{max} occurs at the pulse center and is given by $\Phi_{NL}^{max} = \gamma|A(0,0)|^2 z = \gamma P_0 z$. One can see that the nonlinear length represents the propagation distance at which $\Phi_{NL}^{max} = 1$. Since the nonlinear phase shift Φ_{NL} depends on the initial pulse shape, it varies nonlinearly with time t. This implies that the instantaneous optical frequency differs across the pulse from its central value ω_0. The frequency chirp is given by

$$\delta\omega(t) = \omega(t) - \omega_0 = -\frac{\partial\Phi_{NL}}{\partial t} = -\frac{\partial|A(0,t)|^2}{\partial t}\gamma z \qquad [13]$$

The modification of the phase of the wave envelope by itself is called self-phase modulation. The frequency chirp increases with the propagated distance, thus implying that new frequencies are continuously generated as the pulse propagates through the fiber. This spectral broadening depends on the initial pulse shape. Figure 2 shows the variation of Φ_{NL} and the corresponding induced frequency chirp across the pulse at $z = L_{NL}$ for the case of an initial Gaussian pulse.

The SPM-induced chirp exhibits several interesting features. $\delta\omega$ is negative near the leading edge (red shift) and is positive near the trailing edge (blue shift). The chirp is linear (and increases) in the central region of the pulse. In fact, the chirp $\delta\omega$ at a given propagation distance z depends on the initial chirp. As Figure 3 shows, at a sufficiently long propagated distance, the SPM-induced spectrum exhibits several peaks due to interference effects across the pulse. Indeed as Figure 2 shows, the same frequency chirp occurs at two distinct times associated with two distinct nonlinear phase shifts.

The spectrum width can be estimated by calculating the maximum value $\delta\omega_{max}$ of the frequency chirp. For an initial unchirped Gaussian pulse one obtains

$$\delta\omega_{max} \approx \frac{0.86\gamma P_0 z}{\delta_0} \qquad [14]$$

Thus, the spectral width increases linearly with the propagated distance z and the input peak power P_0, and is inversely proportional to the initial pulse width δ_0. The SPM can be detrimental for optical communication systems. The SPM broadens the spectrum of the signal and makes it then more susceptible to GVD effects. Note that in wavelength division multiplexing (WDM) systems, the phase modulation of a given channel can come not only from the power in the considered channel itself (SPM) but also from the power in a different channel of the WDM system (CPM, i.e., cross-phase modulation). By appropriate dispersion compensation, the impact of SPM and CPM can be significantly reduced. On the other hand, the SPM, combined with dispersive effects, leads to very useful effects such as pulse compression, or the generation of optical solitons (described below).

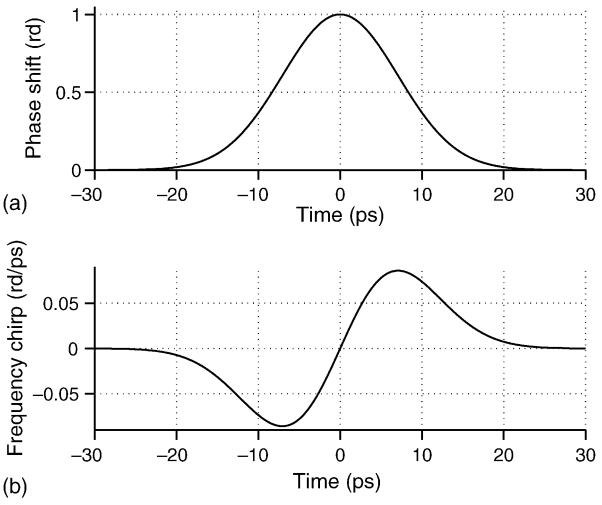

Figure 2 Temporal variation of the nonlinear phase shift (a) and the corresponding frequency chirp induced by SPM (b), for a Gaussian pulse.

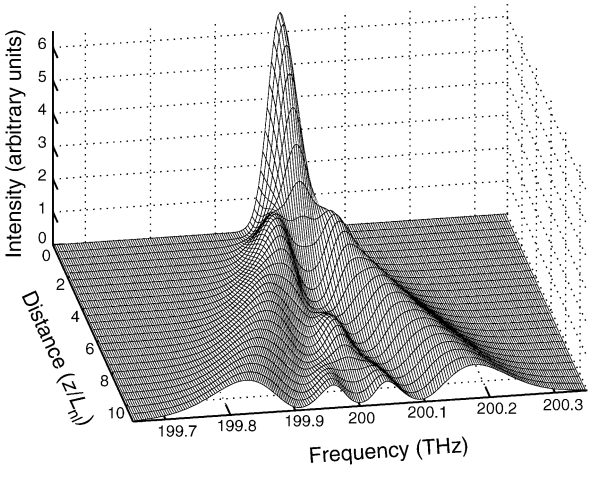

Figure 3 Evolution of the SPM-induced spectral broadening of an initially unchirped Gaussian pulse, as a function of the propagation distance. Here the normalized distance is z/L_{NL}.

Optical Solitons

Bright Solitons

Soliton propagation results fundamentally from a delicate balance between two phenomena: GVD and SPM. As we mentioned above, the GVD causes the spectral components of the pump to move at different velocities, thus leading to a temporal broadening of the pulse as shown in Figure 1 in the case of a Gaussian input pulse. Moreover, eqn [10] shows that the effect of GVD on a propagating Gaussian pulse is associated with a linear frequency chirp $\delta\omega$ and a parabolic temporal phase, proportional to β_2. On the other hand, eqn [12] shows that the SPM induces a frequency chirp across the pulse proportional to the temporal derivative of the pulse intensity. The chirp induced by SPM is then linear only in the central region of the pulse as long as the initial pulse shape is nonparabolic. As a consequence a Gaussian input pulse cannot propagate in a distortion-free manner since the GVD for anomalous dispersion ($\beta_2 < 0$) is able to completely cancel the intensity-dependent phase shift from SPM only over the central region of the pulse. On the other hand we show below that, in the anomalous dispersion regime, the exact cancellation of the nonlinear and dispersive temporal phase components (and corresponding chirps) is obtained in the case of the propagation of a hyperbolic secant pulse, which corresponds to the fundamental bright optical fiber soliton.

We consider the propagation of an unchirped hyperbolic secant pulse at a wavelength of 1.55 μm in a standard telecommunications fiber with $\beta_2 = -21 \times 10^{-3}$ ps^2 m^{-1} and $\gamma = 1.2 \times 10^{-3}$ W^{-1} m^{-1}. The input pulse at $z = 0$ is given by $A(0,t) = \sqrt{P_0}$ sech (t/δ_0) with $\delta_0 = 10$ ps and $P_0 = 175$ mW. With this choice of parameters the dispersion length is equal to the nonlinear length, i.e. $L_D = L_{NL} = 4.76$ km. In fact, these conditions correspond to those which would support a propagating soliton. However, let us consider first how SPM and GVD modify the incident pulse when acting independently. Figure 4 shows numerically computed results from the solutions of eqns [12] and [8] to illustrate the effects of nonlinear and dispersive evolution over a range of propagation distances. The figure shows the pulse intensity as well as the time-dependent phase and the corresponding frequency chirp. The evolution is clearly very different in the presence of only nonlinear or dispersive effects. Nonlinear SPM alone induces no change in the temporal intensity of the pulse, but the magnitudes of the SPM-induced phase and chirp increase with propagation distance. In contrast, GVD induces changes in both the intensity and the phase of the pulse as it propagates, and the temporal broadening with propagation is associated with a significant change in the functional forms of the phase and frequency chirp. In particular, whilst for large propagation distances it can be seen that GVD induces a parabolic temporal phase and corresponding linear chirp, this is clearly not the case for small propagation distances. This result strongly differs from that obtained for a propagating Gaussian pulse for which the temporal phase is always parabolic. In the context of soliton propagation, the results in Figure 4b are of particular significance, since they clearly show that at $z = L_D/10$ where neither SPM nor GVD noticeably modify the pulse intensity profile, the SPM and GVD-induced phases and frequency chirps have qualitatively similar forms, yet opposite sign. The split-step Fourier method demonstrates that over a sufficiently small propagation distance (e.g., $\delta z = L_D/10$) the effects of nonlinearity and dispersion can be considered to act independently on a propagating pulse. This suggests that, over the propagation segment ($0 < z < \Delta z$), the phases are capable of cancelling each other across the entire pulse profile. It is obvious that, if the effects cancel over this distance, then the propagation in the following segment will begin from the same initial condition of an unchirped pulse which was the case at $z = 0$. The nonlinear and dispersive phase components will therefore continue to cancel over successive iterations for an arbitrary length of fiber, and we thus obtain a simple physical interpretation to explain the distortion-free propagation of an optical soliton. Thus, the combined effects of GVD and SPM can prevent the occurrence of a frequency chirp across the pulse. In this situation the pulse propagates with a constant temporal profile. Such light pulses are called optical solitons.

Mathematically, the basic NLSE, eqn [5], belongs to a remarkable class of integrable nonlinear equations, which can be solved exactly for an arbitrary initial condition by means of the inverse scattering method. The solutions depend strongly on the sign of dispersion, and the relative importance of dispersive and nonlinear effects, measured by a dimensionless parameter N:

$$N^2 = \frac{L_D}{L_{NL}} = \frac{\gamma P_0 \delta_0^2}{|\beta_2|} \qquad [15]$$

In the anomalous dispersion regime ($\beta_2 < 0$) the NLS equation admits envelope-soliton solutions. The soliton order is given by the parameter N. Only the fundamental soliton, defined by $N = 1$, can propagate in the fiber with a constant profile, as schematically represented in Figure 5.

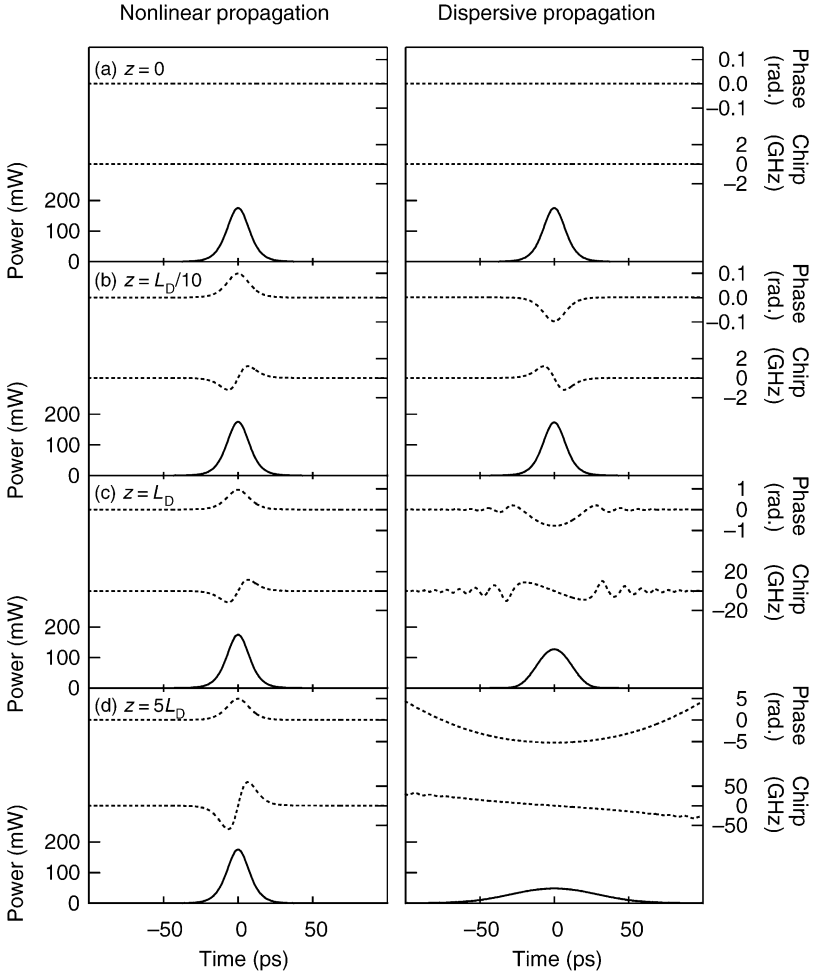

Figure 4 Numerical results showing nonlinear (left column) and dispersive (right column) propagation in an optical fiber, with parameters as described in the text, and for propagation distances as indicated. The solid lines show the pulse intensity (left axis) whilst the dashed lines show the calculated phase (right axis, top) and chirp (right axis, bottom). Constant phase offsets have been removed for clarity.

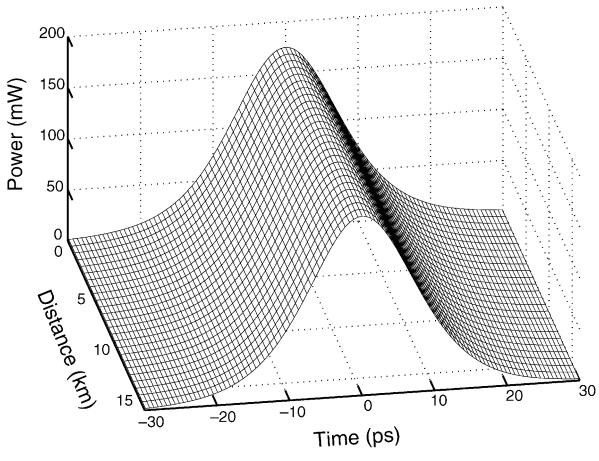

Figure 5 Temporal evolution of the power of a fundamental bright soliton, as a function of the propagation distance. The simulation parameters are the following: input peak power $P_0 = 67$ mW, $\beta_2 = -20$ ps^2 km^{-1}, $\gamma = 3 \times 10^{-3}$ m^{-1} W^{-1} and $\delta_0 = 10$ ps. The nonlinear length is $L_{NL} = 5$ km.

For the fundamental soliton, dispersion and nonlinearity exactly balance each other in a way such that neither the pulse shape nor the pulse spectrum change during the pulse propagation. The fundamental soliton ($N = 1$) is given by

$$A(z,t) = \sqrt{P_0}\,\mathrm{sech}(t/\delta_0)\,\exp(\mathrm{i}\gamma P_0 z/2) \qquad [16]$$

where the peak power required to generate this soliton is determined by $L_D = L_{NL}$, and given by

$$P_0 = \frac{|\beta_2|}{\gamma\delta_0^2} \qquad [17]$$

Note that the phase of this bright soliton remains constant across the entire pulse. For a standard single-mode fiber (SMF), at 1.55 μm wavelength, typical values of the dispersion and nonlinear parameters are $\beta_2 = -21$ ps^2 km^{-1} and $\gamma = 1.2 \times 10^{-3}$ W^{-1} m^{-1}, respectively.

So, the peak power required to propagate a fundamental soliton with pulse width $\delta_0 = 10$ ps, is $P_0 = 175$ mW. This soliton is represented in Figure 5. A further reduction of P_0 can be obtained by using dispersion-shifted fibers (DSF), for which the dispersion can be significantly reduced to values of the order of $1\ \text{ps}^2\,\text{km}^{-1}$. In this situation, the power required to create a soliton reduces to $P_0 = 8.3$ mW. Thus, fundamental solitons can be generated at power levels that are easily obtainable from conventional laser diodes. The first experimental observation of soliton propagation in optical fibers was reported in 1980 by Mollenauer, Stolen and Gordon.

Note that all the higher-order solitons ($N > 1$) execute a recurrent deformation during their propagation, as illustrated in Figure 6 in the case of the second-order soliton ($N = 2$).

Dark Solitons

In the normal dispersion regime ($\beta_2 > 0$) the chirps induced by GVD and SPM reinforce each other and thus make the hyperbolic secant pulse more susceptible to temporal broadening. Thus, in the normal dispersion regime bright solitons cannot propagate. However, in this case the NLS equation, eqn [5], admits a hole-soliton solution. In other words, the intensity profile of this soliton exhibits a dip in a uniform background, as represented in Figure 7.

Mathematically, this hole-soliton, commonly called a dark soliton, takes the following form:

$$A(z,t) = \pm\sqrt{P_0}\,\tanh(t/\delta_0)\,\exp(\mathrm{i}\gamma P_0 z) \qquad [18]$$

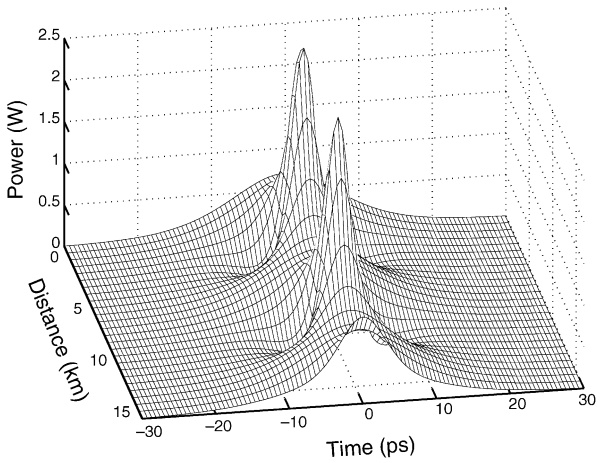

Figure 6 Temporal evolution of the power of a second-order soliton, as a function of the propagation distance. The simulation parameters are the following: input peak power $P_0 = 267$ mW. The fiber parameters are the same as in Figure 5. The nonlinear length is $L_{\text{NL}} = 1.25$ km.

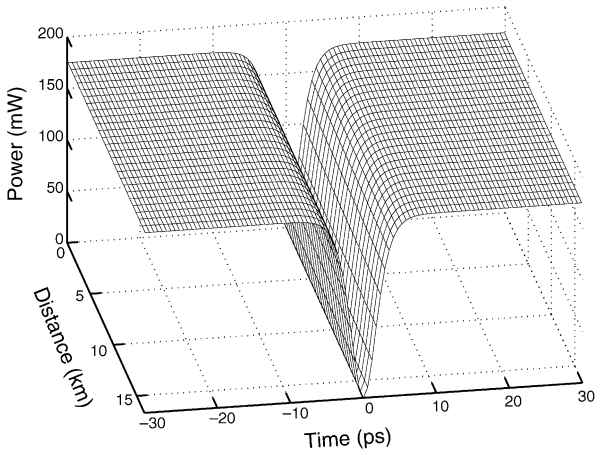

Figure 7 Temporal evolution of the power of a dark soliton, as a function of the propagation distance, for an input peak power $P_0 = 67$ mW.

As eqn [18] shows, the amplitude of the dark soliton is given by an odd function of time. Thus its phase exhibits an abrupt π jump at the dip center, thus implying that dark solitons are chirped. The phase between each jump is constant. Note that there exist other soliton solutions that are similar to the dark soliton, but for which the intensity at the dip center does not fall to zero and the phase variation is more gradual and smaller. These solutions are often called gray solitons.

A common feature of bright and dark solitons is their robustness. This property is very important for ensuring practical applications in optical communications. Moreover, optical solitons emerge unchanged from collision processes. However, dissipative perturbations such as material loss or Raman scattering can destroy such solitons.

Dispersion-Managed Solitons

As we mentioned above, the fundamental soliton is based on a delicate balance between dispersion and nonlinearity, through the relation $L_{\text{D}} = L_{\text{NL}}$. In addition, the existence of this soliton requires that only these two effects are present in the fiber. But in practice, additional linear and nonlinear effects such as fiber losses, Raman scattering, or third-order dispersion, are always present in the fiber. In particular, the fiber losses cause the soliton power to continually decrease during the propagation. The use of lumped amplifiers along the transmission line allows one to compensate for the power loss, but does not prevent the occurrence of chirp. As a consequence, the fundamental soliton does not survive over long distances (a few tens of kilometers), without in-line control. Moreover, this soliton is not stable

against phenomena such as CPM and FWM processes that occur unavoidably in WDM systems. The CPM between the pulses in a given channel and the pulses in other channels induce a frequency chirp (in the considered channel), which is converted into amplitude variations by the fiber dispersion. The FWM induces energy-exchange processes between different channels, which lead to pulse distortions.

A new transmission scheme, called *dispersion management*, was recently proposed to resolve the above-mentioned limitations. Basically, the dispersion-management technique utilizes a transmission line with a periodic dispersion map, such that each period is built up by two types of fibers, generally with different lengths and opposite group-velocity dispersion. Whereas the fundamental soliton requires total cancellation of the chirp at each propagation distance, the dispersion-managed (DM) soliton induces a small variation of the chirp, with a zero mean value over each period of dispersion management.

The DM soliton exhibits major differences with respect to the fundamental bright soliton. First, whereas the fundamental bright soliton possesses a smooth profile (as Figure 5 shows), the profile of the DM soliton exhibits an internal oscillatory structure, with several side-lobes on each side of the soliton's center. A typical representation of a DM-soliton profile is shown in Figure 8, at the free-chirp point of the dispersion map. Another outstanding difference is the following: whereas the fundamental soliton propagates with a constant profile, the DM soliton executes a periodic deformation, with a period that coincides with that of the dispersion map. The minimum value of the soliton's width occurs at the free-chirp point. From this point, the soliton's width can execute several oscillations within one dispersion map, with a peak value that can be quite large compared with the width at the free-chirp point. Figure 9 illustrates the propagation of a DM soliton within one dispersion map of a lossless DM line.

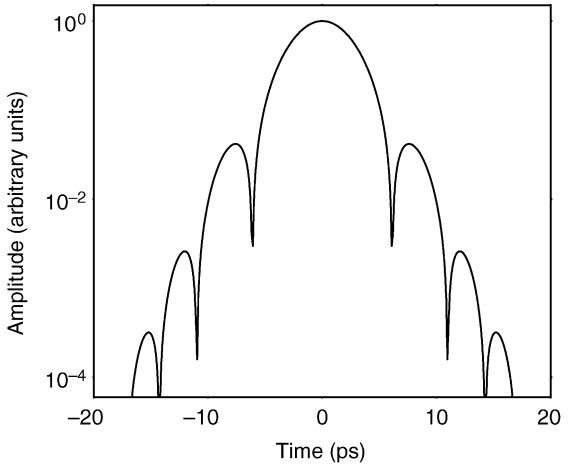

Figure 8 Plot showing the profile of a DM soliton at the free-chirp point of a typical DM line made up of 20.5 km of anomalous-dispersion fiber [$\beta_2 = -1.5 \times 10^{-3}$ ps^2 m^{-1}, $\gamma = 1.4 \times 10^{-3}$ W^{-1} m^{-1}], and 19.5 km of normal-dispersion fiber [$\beta_2 = 1.5 \times 10^{-3}$ ps^2 m^{-1}, $\gamma = 1.4 \times 10^{-3}$ W^{-1} m^{-1}].

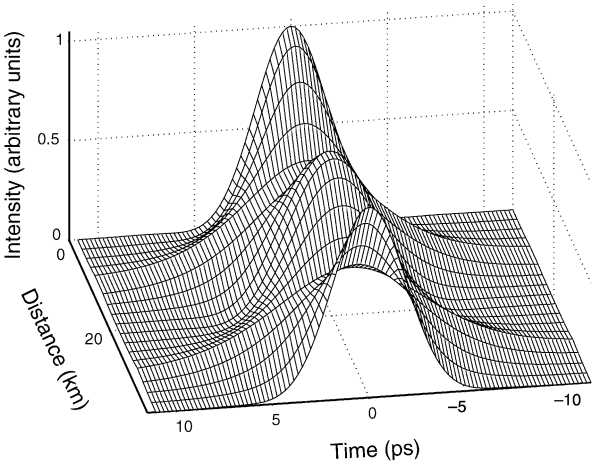

Figure 9 Plot showing the evolution of the DM soliton's profile as a function of the propagation coordinate z.

Recent experiments have demonstrated that in this new transmission scheme the pulse propagation becomes much more stable than fundamental solitons against linear and nonlinear effects such that SPM, FWM, CPM, or third-order dispersion. The DM transmission lines are currently subject to intense research with a view both to upgrade the capacity of existing terrestrial networks, and to design submarine fiber systems with ultrahigh capacity.

Modulational Instability

In optical fibers, the interaction between nonlinear and dispersive effects may lead to modulational instability (MI), a phenomenon in which a continuous or quasicontinuous wave undergoes a modulation of its amplitude or phase in the presence of noise or any other small perturbation. The perturbation can originate from quantum noise (spontaneous-MI) or from a frequency shifted signal wave (induced-MI). MI was observed for the first time by Tai, Hasegawa and Tomita in 1986 for a single pump wave propagating in a standard nonbirefringent fiber (scalar MI). Scalar MI occurs only when the group velocity dispersion (GVD) is negative (anomalous dispersion regime). Modulational instability in eqn [5] is examined through a linear stability analysis (LSA)

of its steady state solution

$$A = \sqrt{P_0}\,\exp[\mathrm{i}\gamma P_0 z] \qquad [19]$$

Equation [19] shows that the power remains constant through propagation along the fiber. The linear stability of the steady state solution is examined by looking into the system in the presence of small amplitude and phase perturbations *a;* that is, we consider

$$A = (\sqrt{P_0} + a)\,\exp[\mathrm{i}\gamma P_0 z] \qquad [20]$$

Then, the linearization of the NLSE with respect to a yields

$$\frac{\partial a}{\partial z} + \frac{\mathrm{i}}{2}\beta_2\frac{\partial^2 a}{\partial t^2} = \mathrm{i}\gamma P_0(a + a^*) \qquad [21]$$

Then one can assume for the perturbation a modulational ansatz with wavenumber K and frequency Ω, of the form

$$a(z,t) = u\cos(Kz - \Omega t) + \mathrm{i}v\sin(Kz - \Omega t) \qquad [22]$$

Substitution of eqn [22] into eqn [21] leads to the following dispersion relation for the perturbation

$$K^2 = \frac{\beta_2^2\Omega^2}{4}\left[\Omega^2 + \frac{4\gamma P_0}{\beta_2}\right] \qquad [23]$$

The MI phenomenon manifests itself by an exponential growth of the amplitude of the perturbation. This behavior occurs when the wavenumber K possesses a nonzero imaginary part. The dispersion relation [23] clearly shows that MI strongly depends on the sign of the dispersion. For normal dispersion ($\beta_2 > 0$), K is always real and the steady state is stable, whereas in the anomalous dispersion regime, MI appears for $\Omega < \Omega_c = \sqrt{4\gamma P_0/|\beta_2|}$. The importance of the phenomenon is measured by a power gain defined by

$$g(\Omega) = 2|\mathrm{Im}(K)| = |\beta_2|\Omega\sqrt{\Omega_c^2 - \Omega^2} \qquad [24]$$

Figure 10 shows the MI-gain spectra at three power levels with fiber parameters appropriate for standard silica fibers at $\lambda_0 = 1.319\ \mu\mathrm{m}$.

The peak value of the gain, $g_{\max} = 2\gamma P_0$, occurs at a frequency

$$\Omega_{\mathrm{opt}} = \sqrt{\frac{2\gamma P_0}{|\beta_2|}} \qquad [25]$$

called the optimal modulational frequency. In practice, when the perturbation corresponds to quantum noise, the spectral components that are amplified by the MI-process are close to Ω_{opt}. Here, as shown by Figure 11, the MI phenomenon leads to two sidebands that are situated symmetrically with respect to the pump, at frequency detunings of $\approx \pm\Omega_{\mathrm{opt}}$ (see Figure 10 for a pump peak power $P_0 = 3$ W).

In the time domain, induced-MI leads to the break-up of the quasi-cw pump wave into a train of ultrashort pulses. The repetition rate of the pulses is determined by the frequency detuning between the signal and the pump (i.e. the modulational frequency). The temporal shape of these ultrashort pulses depends not only on the powers

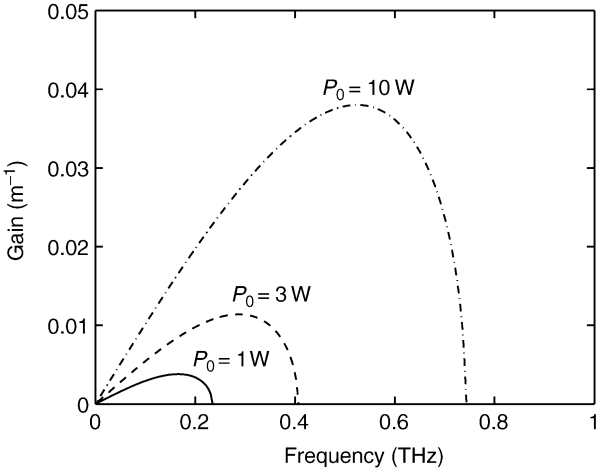

Figure 10 Spectral profiles of MI gain g for a pump peak power $P_0 = 1$ W (solid), 3 W (dashed) and 10 W (dot-dashed). The fiber parameters are $\beta_2 = -3.5\ \mathrm{ps}^2\ \mathrm{km}^{-1}$ and $\gamma = 1.9 \times 10^{-3}\ \mathrm{m}^{-1}\mathrm{W}^{-1}$.

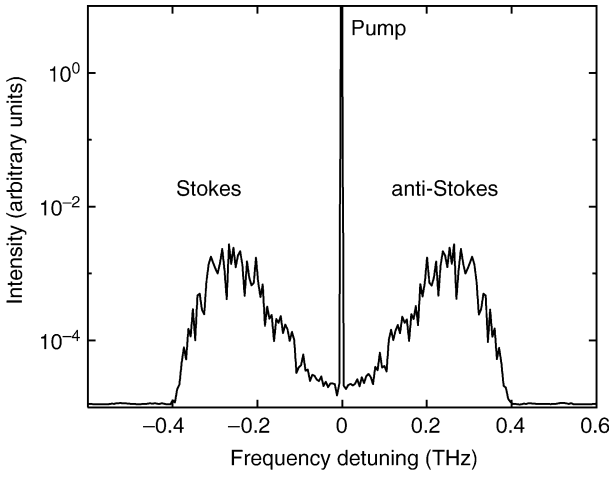

Figure 11 Spontaneous modulational instability spectrum (i.e., parametrically amplified spontaneous noise), as obtained for a peak pump power $P_0 = 3$ W and a fiber length $L = 1$ km. The fiber parameters are the same as in Figure 10.

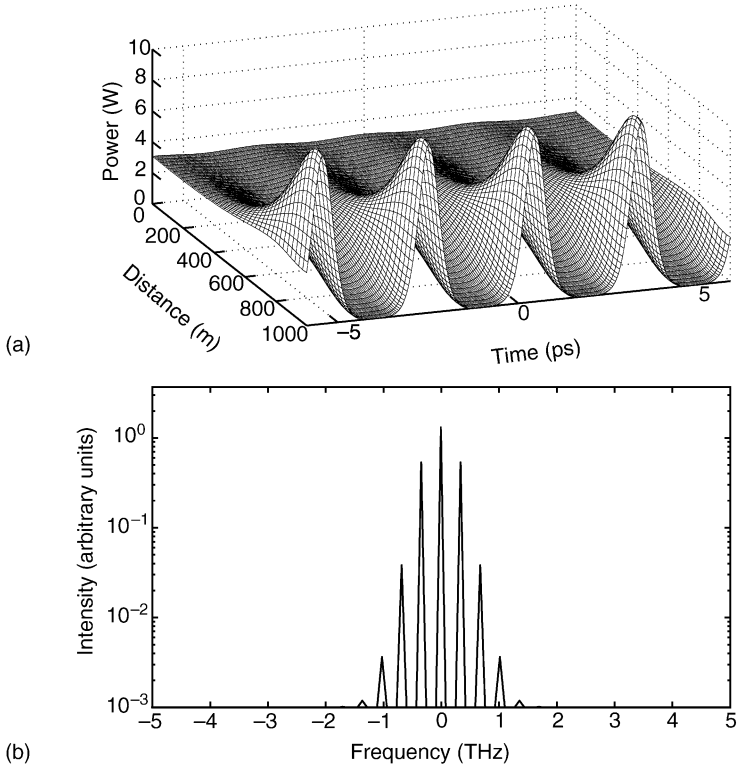

Figure 12 (a) Theoretical temporal evolution of the power for induced-MI, as a function of the propagation distance. (b) Output power spectrum in logarithmic intensity scale. The pump (signal) power is 3 W (0.5 mW), the pump-signal frequency detuning is 0.34 THz, and the fiber length is 1 km. The fiber parameters are the same as in **Figure 10**.

of the input waves but also on the modulational frequency. In particular, trains of bright and dark solitons with a terahertz repetition rate have been generated by MI in optical fibers. **Figure 12a** shows theoretically the evolution of a small initial modulation.

As **Figure 12a** shows, MI causes a small initial perturbation to evolve into a periodic pulse train, whose period is inversely proportional to the frequency spacing Δf between the pump and signal waves. Thus the technique of induced-MI can be exploited for generating high-repetition-rate ultrashort pulse trains. As shown in **Figure 12b**, such pulse train generation manifests itself in the frequency domain by the growth of a cascade of sidebands. The number of harmonics ($n\Delta f$) is determined by the temporal shape of the generated pulses and the initial conditions at the fiber input.

Cross-phase modulation (CPM) between two modes can be used to extend the instability domain to the normal dispersion regime (positive GVD). This is achieved by using orthogonally polarized pump waves. This CPM-induced MI is called vector modulational instability. The optical field evolutions are described by two coupled NLS equations. Several experiments involving two polarization modes, or two spatial modes, have been done in order to observe MI in the normal GVD regime.

Conclusion

The invention of soliton transmission, predicted in 1973 and experimentally demonstrated in 1980, is one of the major discoveries made in the area of optical telecommunication. Although from the period of invention of optical solitons up to very recent years the main line of research activities was based on the concept of the 'classical soliton', which represents an exact balance between the fiber group-velocity dispersion and its intensity-dependent refractive index, most recent experimental and theoretical developments focus on dispersion-managed solitons. It is now widely recognized that DM solitons in fiber-optic links are the most promising way both to upgrade the capacity of existing terrestrial telecommunication networks and to design submarine fiber systems. Most of the current research and development activities in this context aim to develop a non-empirical methodology of designing ultrahigh-speed DM fiber systems.

List of Units and Nomenclature

Dispersion length L_D [m]
Group velocity dispersion coefficient β_2 [$ps^2\,km^{-1} = 10^{-27}\,s^2\,m^{-1}$]
Nonlinear length L_{NL} [m]
Nonlinear parameter γ [$W^{-1}\,m^{-1}$]
Nonlinear refractive index n_2 [$m^2\,W^{-1}$]
Optical intensity I [$GW\,cm^{-2} = 10^9\,W\,cm^{-2}$]

CPM: cross-phase modulation
DM Soliton: dispersion-managed soliton
FWM: four-wave mixing
GVD: group velocity dispersion
LSA: linear stability analysis
MI: modulational instability
NLS (E): nonlinear Schrödinger (equation)
SPM: self-phase modulation
WDM: wavelength division multiplexing

Soliton Communication Systems

Introduction

In 1973 Hasegawa and Tappert proposed that optical soliton pulses in fibers could exist. A soliton is a propagating wave packet that is localized in the sense that it does not spread its energy during propagation, and with the additional property that it is so stable that it can collide with other solitons and emerge unaffected with respect to energy, shape, and momentum after the collision. Solitons are based on some kind of nonlinearity in the system, and for optical fibers the weak Kerr nonlinearity (which makes the refractive index increase in proportion to the optical intensity) can counteract the pulse broadening induced by group-velocity dispersion (GVD). The two effects can form a stable balance in the form of a soliton pulse, which then propagates without changing shape.

Due to the lack of short-pulse laser sources at wavelengths above 1.3 μm, and low-loss silica fibers, it took another seven years for optical soliton pulses to be experimentally verified. In an experiment by Mollenauer, Stolen, and Gordon in 1980, soliton pulse transmission over 700 m fiber was demonstrated. During the 1980s soliton research aimed towards the use of solitons as information carriers in optical communications, and in 1990 the first data transmission experiment using solitons (2.8 Gb/s over 23 km of fiber) were reported by Iwatsuki *et al*.

During the 1990s, soliton-based communication systems have matured, an important reason being the development of the erbium-doped fiber amplifier (EDFA), which made high power levels commercially available. The most recent developments have been towards the use of solitons in alternating dispersion maps (so-called dispersion management), and such systems have reached performance levels near commercialization.

It should be stressed that fiber soliton research has been almost exclusively devoted to single-mode fibers at a wavelength of 1550 nm. In principle, solitons can also be used to counteract mode dispersion in multimode fibres, but that generally requires unrealistically high peak powers, and is therefore regarded to be of less interest. Similarly, solitons with wavelengths around 1300 nm in single-mode fibers have been

considered, but found to be of less interest due to the lack of low-noise optical amplifiers in this spectral range. Another kind of soliton, the so-called dark soliton, can also be generated in single-mode fibers. However, dark solitons have only been used as information carriers in a very limited number of experiments, and will also be omitted from this discussion.

In the present review we will discuss both theoretical and experimental aspects of soliton transmission. We will distinguish between conventional solitons, which have constant dispersion during transmission, and dispersion-managed solitons (although solitary waves would be the proper mathematical name) for which the dispersion varies periodically during transmission.

Conventional Fiber Solitons

Group-velocity dispersion means that the group velocity of the light changes with the optical frequency, and it is usually defined as the second derivative of the propagation constant β with respect to the angular frequency ω, and denoted β_0'' [$\mathrm{ps^2\,km^{-1}}$]. Standard single-mode fibers have a $\beta_0'' \approx -20$ [$\mathrm{ps^2\,km^{-1}}$] around a wavelength of 1550 nm, whereas dispersion-shifted fibers (DSFs) have β_0'' close to zero in the 1550 nm region. The dispersion is defined with respect to sign, so that the GVD is said to be normal if the group velocity decreases with frequency (i.e., $\beta_0'' > 0$), and anomalous if the group velocity increases with frequency (i.e., $\beta_0'' < 0$). A pulse propagating in a dispersive fiber will broaden with propagation distance at a rate proportional to the product of β_0'' and the spectral width of the pulse. In a communication system such a broadening is devastating, since neighboring pulses will interfere and disperse power into adjacent bit slots. The problem is increased for high data rates (as this requires short pulses with broad spectra) and/or long transmission distances.

The nonlinearity in optical fibers manifests itself as a dependence of the refractive index with power, and is known as the optical Kerr effect. For pulse propagation the Kerr effect will give rise to self-phase modulation (SPM), which means that the pulse will get a phase modulation proportional to its own intensity. Mathematically speaking, the amplitude of an optical pulse $u(0, t)$ [$\mathrm{W^{1/2}}$] launched at $z = 0$ will evolve according to $u(z,t) = u(0,t)\exp(-\mathrm{i}\gamma z|u(0,t)|^2)$, where γ [$\mathrm{W^{-1}\,km^{-1}}$] is the nonlinear coefficient of the fiber, z [km] is the propagation distance along the fiber, t [ps] is the time coordinate, and $|u(z, t)|^2$ [W] is the power level of the light. The value of γ varies between different fiber types due to the dependence on the core area of the fiber, but for standard single-mode fibers, in the 1550 nm region, it is approximately 2.2 $\mathrm{km^{-1}\,W^{-1}}$.

Taking both self-phase modulation and dispersion into account, one can derive a propagation equation for light, known as the nonlinear Schrödinger (NLS) equation. Of particular importance for the solution to the NLS equation is solitons, which is a solution that propagates without dispersive broadening. The soliton solution arises as a result of a cancellation of the dispersion and the self-phase modulation effects, and it can only be formed when the dispersion is anomalous. For normal dispersion the nonlinearity and the dispersion will instead act together to increase the spectral broadening of the pulse. The soliton solution of duration t_0 and dispersion β_0'' reads

$$u_{\mathrm{sol}}(z,t) = \sqrt{\frac{1}{\gamma L_{\mathrm{D}}}}\,\mathrm{sech}\left(\frac{t}{t_0}\right)\exp\left(-\mathrm{i}\frac{z}{2L_{\mathrm{D}}}\right) \qquad [1]$$

where the dispersive length is $L_{\mathrm{D}} = t_0^2/|\beta_0''|$ [km]. The soliton peak power P_{s} [W] and energy E_{s} [J] can be expressed as $P_{\mathrm{s}} = |u_{\mathrm{sol}}(z,0)|^2 = |\beta_0''|/\gamma t_0^2$ and $E_{\mathrm{s}} = 2P_{\mathrm{s}}t_0 = 2|\beta_0''|/\gamma t_0$.

The fact that solitons are not broadened by dispersion will make them ideally suited as information carriers in a communication system. However, the solitons are affected by various perturbations that will affect the balance by dispersion and nonlinearity. Unless proper care is taken in the design of the system, those perturbations can destroy the performance of the communication system. Next, we will review the most important perturbations and design issues of soliton-based communication systems.

Solitons in the Presence of Third-Order Dispersion

The third-order dispersion (TOD), or the dispersion slope, is modeled with the derivative of the GVD, β_0''' [$\mathrm{ps^3\,km^{-1}}$], which is typically 0.1 $\mathrm{ps^3\ km^{-1}}$ in standard and dispersion-shifted fibers. For solitons in dispersion-shifted fibers the effect of the dispersion slope is increasingly important the closer the solitons are to the zero dispersion wavelength.

When a soliton is placed close to the zero-dispersion wavelength, it will emit radiation in the normal dispersion regime of the spectrum, lose energy, and recoil further into the anomalous dispersion region so that the radiation stops and a stable soliton is formed. As a design criterion $\beta_0'''/(|\beta_0''|t_0) < 0.24$ have been suggested for this phenomenon to provide negligible energy loss.

Solitons in the Presence of Amplification and Loss

The most important property that has been neglected in the derivation of the NLS equation for optical

pulses is the effect of loss. The loss will decrease the power and hence the nonlinearity so that the balance sustaining the soliton is no longer maintained. As a result of the loss (which is of the order of 0.2 dBkm^{-1} in standard transmission fibers) the soliton pulse will be broadened. Partly, this can be circumvented by requiring the launched peak power of the soliton after each amplifier to be such that the path-average power between the amplifiers equals the soliton power, P_s. The peak power P_{peak} falls off as $\exp(-\alpha z)$, where $\alpha = 0.042$ km^{-1} is the fiber loss coefficient, and the average peak power over one amplifier span is then $P_{peak}\ (1 - \exp(-\alpha L_a))/\alpha L_a = P_{peak}(G - 1)/G\ \ln(G) = P_s$, where $G = \exp(\alpha L_a)$ is the gain of each amplifier and L_a [km] is the amplifier spacing.

Nevertheless the periodic fluctuation of power and width over each amplifier length may cause the solitons to become unstable and lose power to dispersive wave radiation. To minimize this loss a useful design criterion is that the amplifier length L_a should be smaller than the dispersive length, L_D.

Sources of Timing Jitter

Another transmission obstacle is the various sources of random movement of the pulse in the bit slot, i.e., timing jitter of the pulses in the data transmission link. There are various sources of timing jitter, e.g., soliton interaction, Gordon–Haus, acoustic, and wavelength division multiplexing collision induced jitter.

Soliton interactions

Solitons, being nonlinear pulses, will interact with adjacent pulses in the pulse train. The interaction between solitons of the same polarization state and wavelength is phase sensitive so that in-phase solitons will attract each other whereas out-of-phase solitons will repel each other. To reduce this effect the solitons must be sufficiently spaced in the data stream. A typical design condition is that the pulse width of the solitons are one fifth of the bit slot, or one fifth of the inverse bit rate. A straightforward way of reducing the interaction is to have alternating amplitudes of the soliton in the pulse train, and the solitons can then be packed more densely.

Orthogonally polarized solitons interact substantially less, since it is the intensity overlap that causes the interaction, rather than the amplitude overlap as for copolarized solitons. In polarization multiplexed systems where adjacent pulse have orthogonal polarization it is usually enough with half the above separation, i.e., a pulse duration of 2.5 less than the bit separation.

Gordon–Haus jitter

Noise from the in-line amplifiers will give rise to a small jitter in the carrier frequency of each soliton, which, via the dispersion, will alter the group velocity and hence affect the arrival time of each pulse. This is known as the Gordon–Haus effect, and it has to be accounted for in long-distance systems. The variance of the timing jitter is proportional to the ratio of the power spectral density of the noise to the energy of the soliton, and also proportional to the transmission distance cubed. The fact that Gordon–Haus jitter grows cubically with distance makes it particularly important at transoceanic lengths, typically exceeding 1 Mm.

Acoustic jitter

The electrostriction nonlinearity in the fiber gives rise to a mechanical pressure proportional to the optical intensity, which in turn modifies the refractive index of the fiber. In particular, an intense optical pulse like a soliton will give rise to a pressure (acoustic) wave moving radially outwards from the fiber center. The pulses in the wake of this wave will experience a randomly changing local refractive index, and hence (just as for Gordon–Haus jitter) a randomly changing carrier frequency that transforms into a timing jitter. The variance of this jitter will grow as the transmission distance to the power of four.

WDM Considerations

Wavelength division multiplexing (WDM) is another way of increasing the bit-rate of soliton systems. That is, several frequency channels are used for solitons transmission. The problem with WDM transmission using solitons stems mainly from collisions between solitons in the different wavelength channels. In a perfectly ideal NLS equation solitons would collide elastically without changing carrier wavelength. However, the presence of losses and amplification may cause the collisions to be asymmetric if they occur around an amplifier, and the result will be a frequency displacement and a concomitant timing jitter.

Soliton Control

Soliton control is the common name for methods to control the soliton parameters such as wavelength and position, mainly in order to reduce the deleterious timing jitter effects. There are two different approaches: passive and active control.

Passive soliton control has been suggested in the form of filters that are inserted along the transmission path. This helps to keep the soliton wavelength fixed. In this way not only Gordon–Haus and acoustic jitter can be remedied, but also interaction jitter and

WDM-collision-induced jitter. A problem with this kind of filtering is that it defines a spectral region with excess gain, in which amplifier noise will grow excessively. A way around that problem is to slightly shift the center wavelength of the filters along the transmission path. In that way the solitons will follow the frequency shift, but the linear noise will not. Such sliding filter experiments have demonstrated 8×10 Gb/s WDM soliton transmission over 10 Mm.

Active control usually acts in the time domain by using phase or amplitude modulators to retime and reshape the solitons. Using this technique, 10 Gbit/s over unlimited distances has been demonstrated. However, this kind of active reshaping of the pulses suffers from the same drawbacks as conventional electronic regeneration, i.e., incompatibility with WDM, complexity, and high cost.

Dispersion-Managed Solitons

Introduction

In the last years of the 1990s, solitons have become substantially more attractive through the rapidly emerging strategy of improving the performance of soliton transmission with dispersion management (DM). While the DM strategy, which involves altering the local dispersion between a large positive and a large negative GVD such that the average GVD is small, has long been used in linear systems, it was only relatively recently appreciated that the same technique, if properly implemented, gives rise to several very striking improvements over conventional soliton transmission systems. While DM-solitons are clearly nonlinear pulses they are by no means classical solitons.

From a commercial viewpoint, however, the most important benefit with using DM-solitons is that they, in principle, can use the already installed conventional fibers (with zero dispersion at 1300 nm) allowing a much more cost-effective upgrade together with dispersion-compensating fibers (DCF) or chirped fiber gratings, which can be located together with in-line amplifiers at certain intervals in the link.

In Figure 1, an example of breathing in spectral and temporal widths of a DM-soliton can be seen, together with its dispersion map at the bottom.

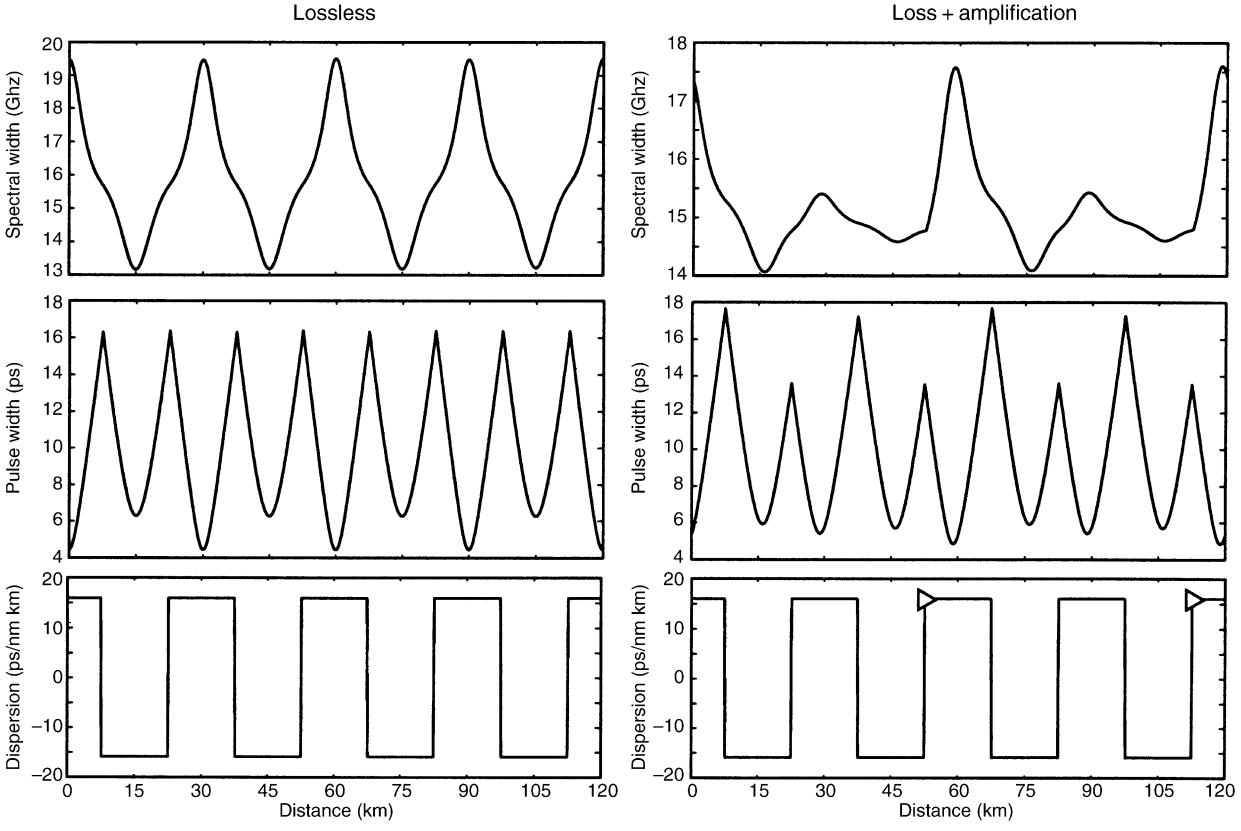

Figure 1 Plot of the spectral width (top), temporal width (middle), dispersion map (bottom) of a dispersion-managed soliton in the lossless case (left column) and the lossy case that is periodically amplified (right column). The positions of the amplifiers are denoted by the small triangles in the plot of the dispersion map.

Two cases are shown; one without fiber attenuation (left column) and one including fiber losses and periodic, lumped amplification every 60 km. One may note the strictly periodic behavior of both the spectral and temporal widths in both cases, and that the evolution of the spectral width is significantly different in the lossy case. This is because a change of the pulse spectrum requires nonlinearities and high power, and the spectral broadening is therefore highest directly after the amplifiers.

Properties

DM-solitons emerged from extensive simulation work, and it was quite surprising to many researchers that the simulations revealed such stable and strictly periodic pulses. The periodicity follows that of the dispersion variation of the system. Usually the system under study has a dispersion map, i.e., a plot of how the GVD varies along the transmission path. The map has a characteristic period (typically 10–100 km) and an average GVD which is significantly lower than the local GVD in the map.

As a result of the massive simulation work done by many groups the following properties of DM-solitons have been found:

- The pulse width, chirp, and spectral width oscillates periodically in the dispersion map. There are two points within the period at which the pulse is chirp-free, and those correspond to local minima of the pulse width. One of those points is the global minimum width, referred to as the 'shortest pulse' below.
- A central parameter that is useful for the characterization of DM-solitons is the map strength, $S = (L_1|\beta_1''| + L_2|\beta_2''|)T_{\mathrm{FWHM}}^2$, where L is the length, β'' is the dispersion, T_{FWHM} is the minimum pulse width in the full width half maximum sense, and the subscripts 1 and 2 refer to the two fibers in the dispersion map. In this example we thus assume the map to consist of two fibers, one with normal and one with anomalous dispersion. Physically the map strength is the number of dispersive lengths the pulse propagates in one period. DM-solitons have been found for map strengths ranging from $S = 0$ (which is the same as conventional solitons) to $S \approx 12$, although this upper limit is a transition regime in which the pulses radiate and perfect periodic evolution never arises.
- DM-solitons have been found for anomalous, normal, and zero average dispersion β'', defined as $\beta_0'' = (L_1\beta_1'' + L_2\beta_2'')/(L_1 + L_2)$. Normal average dispersion is only possible for map strengths above 3.9.
- The shortest pulse shape ranges from hyperbolic secant at $S = 0$ to Gaussian for higher map strengths, and this is also evident from the time-bandwidth product, which increases with S from 0.32 (sech-shape) at $S = 0$ to 0.44 (Gaussian shape) and even higher for large values of S. In addition, the shortest pulse has oscillating tails in the wings.
- The energy of a DM-soliton pulse is enhanced relative to a soliton with the same average dispersion and pulse width.
- The interaction between DM-solitons is less than that of conventional solitons, and an optimum map strength exists that minimizes the interaction.

The fact that DM solitons can work for an average net zero GVD and even for normal dispersion, was a striking and unexpected difference from conventional solitons. This can be understood by the fact that the spectrum is widest in the anomalous dispersion regime (i.e. positive values of the dispersion parameter D, cf. Figure 1), and it has been conjectured that the average dispersion, weighted by the spectral width of the DM-soliton, should always be anomalous. This is then a generalization of the fact that conventional solitons must always have a constant anomalous dispersion.

The technical improvements with DM solitons over conventional ones are numerous. The signal-to-noise ratio is improved since the DM-solitons have a larger peak power than the corresponding conventional solitons. DM-solitons have less Gordon–Haus and acoustic timing jitter, since the system average GVD is much smaller in these systems. A very important added benefit appears in WDM systems. Due to the alteration between large positive and negative GVD along the path, the jitter induced from WDM-soliton collisions is greatly reduced. This, in turn, allows for very dense WDM which will improve the spectral efficiency substantially.

An important practical consequence of using DM-solitons is that they reduce (or eliminate) the need for in-line soliton control such as synchronous modulation or sliding filters. Yet soliton control methods are still applicable and will give improvement in terms of signal-to-noise ratio for DM-solitons as well.

Quite impressive circulating loop experiments including WDM have been reported. For example, 51 densely packed WDM channels each operating at 20 Gb/s were transmitted over 1000 km with 100 km sections of standard fiber, clearly demonstrating the strength of the DM soliton technique.

Quasi-linear Transmission Intrachannel Impairments

As a rule, map strengths in the range 1–8 make best use of the unique features of DM-solitons. This means that the use of installed standard fiber becomes difficult at very high bit-rates (say beyond 30–40 Gb/s) as shorter pulses require a more rapidly (sub-km) varying dispersion map to maintain a proper S-value. If this cannot be maintained, i.e. for S values significantly above 10, one reaches the quasi-linear regime, in which the dispersion significantly dominates the transmission.

In the quasi-linear regime, there are a couple of nonlinear transmission impairments that need to be accounted for and analyzed in more detail. They are the so-called intra-channel effects; intra-channel four-wave mixing (ICFWM), and intra-channel cross-phase modulation (ICXPM), and arise due to the nonlinear interaction between two neighboring pulses. Four-wave mixing (FWM) and cross-phase modulation (XPM) are usually effects associated with WDM transmission. However, the fact that the pulses are chirped and broadened, will cause different frequency components from neighboring pulses within the same wavelength channel to overlap in time, thereby causing FWM and/or XPM within the same channel.

ICFWM arises for two neighboring pulses that, via four-wave mixing (FWM), creates new frequency components that in the time domain will give rise to a new pulse (commonly referred to as a ghost pulse), next to the two. The ghost pulse will then give rise to intersymbol interference and reduction of the eye opening. ICFWM is most prominent for large map strengths and high power.

ICXPM can be viewed as pulse-to-pulse interaction, and physically, it manifests as the frequency shift of one pulse induced by the presence of a neighboring pulse, which, by the dispersion transforms into a timing jitter. The effect can be minimized by selecting proper map strength and pre-chirp of the pulses.

Finally it should be emphasized that these intra-channel impairments will affect also non-soliton systems (e.g., non-return-to-zero (NRZ) modulated systems) if the nonlinearities are significant.

Experiments and Field Trials

Soliton Pulse Sources

When doing soliton experiments, be it conventional or DM-solitons, particular importance is placed on the properties of the pulse source, as it sets the lower limit of the system performance. A high bit-rate soliton pulse source needs to produce low-chirp, low timing-jitter pulses with proper duration (in the ps regime), repetition rate (10–40 GHz), and shape.

One possible choice is gain-switched (GS) laser diodes, possibly with an external cavity for tunability. However, they suffer the drawback of producing pulses that are strongly chirped, asymmetric and often too wide.

For laboratory experiments, fiber ring lasers (FRL) are very attractive, as they provide wavelength and pulse width tunability, besides meeting the above demands. Their drawback is that they are bulky, need active stabilization, and sometimes also temperature control to achieve long-term stability.

Finally it appears quite clear that electro-absorption modulators (EAM), which can be integrated or not with a distributed feedback (DFB) laser, are very useful and simple sources for soliton transmission. While such sources were developed for linear NRZ systems, they have now proven to be near ideal in soliton systems as well. Although EAMs are not commercially available at 40 GHz yet, they are likely to be so soon.

Special considerations need to be taken in DM-soliton systems, however, as the launch condition is different from that for conventional solitons. The pulses should have a linear chirp such that it fits seamlessly in the periodically induced chirp variation along the link. This can be achieved by incorporating a proper length of fiber (or chirped fiber grating) in the transmitter once the overall dispersion map is known.

Loop Experiments

In order to investigate really long distances (megameters) of transmission, loop experiments were developed in the early 1990s. This means that the data pulses are injected in a loop consisting of transmission fiber and amplifier, and then left to propagate a number of laps corresponding to a certain transmission distance. Acousto-optic switches are used to switch the pulse train in and out from the loop at proper time intervals. The drawback of loop experiments is that they may be poor models of reality when it comes to things like dispersion variation along the fiber, polarization mode dispersion (PMD), or various kinds of drift that may arise. In addition, a real system has more options to fine tune, e.g., amplifiers along the transmission line. However, as long as these drawbacks are recognized, loop experiments are very powerful indeed, and invaluable in laboratory evaluations of long-distance transmission.

Field Trials

In the field, there are many transmission link design restrictions and fiber properties which make the systems far from optimal. The actual fiber parameters are nonperiodic with propagation distance as the systems are straight lines rather than relatively short loops. Both loss (in particular when including many contacts and splices along the link) and dispersion might vary significantly along a fiber span. In addition, it may not be possible to tailor the dispersion map and amplifier locations to reach an optimal state. All these examples of nonidealities justify the need for field experiments.

Several soliton field experiments have been conducted over the past few years in Japan by NTT, in the US by MCI/Pirelli, as well as in Europe by ACTS projects, and the results from those experiments are discussed below. It is a good indication that solitons are indeed foreseen as very interesting candidates in commercial systems. Again, it is not very easy to compare the results as the situation in each case differs. All of the systems operated in the 1550 nm range, used optical time division demultiplexing with a 10 Gb/s electronic base rate, and the average loss/km ranged from 0.24 to 0.33 dB/km. Dispersion-shifted fiber was always used, apart from in two cases, where standard fiber was used. One field trial has used DCF for dispersion compensation, which makes this the only DM-soliton field experiment to date.

Polarization multiplexing, for which adjacent pulses have orthogonal polarization, have been used in a few experiments and this serves mainly to allow the use of relatively wide pulses, which in turn allows for larger amplifier spans. Polarization-multiplexing, however, is not as useful if the PMD of the system is high, as then the orthogonally polarized pulses would start to drift statistically in time relative to each other, thereby creating intersymbol interference and increasing the soliton interaction. In the 40 Gb/s cases and above, PMD was found to be the main capacity limiting factor.

Most of the recent experiments used a mode-locked fiber ring laser as a source, mainly because these provide excellent pulse quality as well as tunability in terms of wavelength and pulse width. Other experiments used either gain-switched lasers or electro-absorption modulators.

Future soliton field trials are expected to (1) take advantage of the now well-known strategy of improving soliton transmission performance with dispersion-management, this being very attractive for upgrading existing fiber plants, (2) implement dense WDM (in fiber lines that do not contain dispersion-shifted fibers) to boost aggregate capacity, (3) utilize different forms of in-line control, particularly at high bit rates, and (4) further address the implications of PMD and techniques to combat it. The interesting trade-off between wavelength and time division multiplexing (WDM–TDM) for optimization of overall aggregate capacity will depend on the details of the fiber line parameters.

Future Outlook

To conclude, we note that the motivation for using solitons as information carriers has changed over the years. The property of being resistant to dispersive broadening was originally the main feature, but this was considered less important when dispersion-compensating fibers became commercially available. Instead, this led to the development of the dispersion-managed soliton. The advantages of the DM-soliton over linear transmission are features like the large power which gives a high signal-to-noise ratio. On the other hand, the difference between linear and nonlinear pulses is becoming increasingly fuzzy, and perhaps the distinction should be made between return-to-zero (RZ) and NRZ modulation rather than between linear and nonlinear transmission.

It is nevertheless interesting to note that solitons are now not only considered for oceanic systems but also for shorter terrestrial systems. There are still several challenges and opportunities remaining in order to take full advantage of solitons and to reach a better understanding. Further work is also needed on WDM soliton- and very high-speed TDM soliton-systems. The use of DM-solitons is a very recently established technique and there are thus many issues to consider. These include studies of robustness to deviations of optimum conditions, e.g., improper pulse launch conditions, the impact of nonperiodic dispersion maps and of PMD (both of which are difficult to study in loop experiments), and intrachannel effects. Nevertheless, solitons have now reached a level of maturity such that commercialization seems very near.

List of Units and Nomenclature

Amplifier gain	G	$[-]$
Amplifier separation	L_a	[km]
Average dispersion	β_0''	$[\mathrm{ps}^2\,\mathrm{km}^{-1}]$
Dispersive length	L_D	[km]
Fiber loss coefficient	α	$[\mathrm{km}^{-1}]$
Fiber nonlinear coefficient	γ	$[\mathrm{W}^{-1}\,\mathrm{km} - 1]$
Group velocity dispersion (GVD)	β_0''	$[\mathrm{ps}^2\,\mathrm{km}^{-1}]$

Map strength	S	[−]
Optical field amplitude	$u(z, t)$	[$W^{1/2}$]
Pulse duration	t_0	[ps]
Soliton energy	E_s	[J]
Soliton peak power	P_s	[W]
Third-order dispersion	β_0''	[$ps^3\ km^{-1}$]
Time	t	[ps]
Transmission distance	z	[km]

Introduction

The fact that wave propagation phenomena are intrinsically dispersive, that is localized disturbances tend to spread, is part of our experience. Less well known is the fact that the spreading of wavepackets can be counteracted by the nonlinear response of the host medium. Solitons are wavepackets that exploit this principle, realizing a perfect balance of dispersion and nonlinearity that allows them to self-trap and travel undistorded, or at least to recover their shape periodically, for long (virtually unlimited) distances. More specifically, here we deal with optical temporal solitons constituted by envelopes, or pulses with relatively narrow bandwidths around a carrier optical frequency, whose temporal profile remains unchanged (either strictly or on average) upon propagation. In contrast with spatial solitons predicted earlier and such that nonlinearities are exploited to compensate for diffractive beam spreading even in the two transverse dimensions (i.e., in bulk samples, for details the reader is referred to **Solitons:** Bright Spatial Solitons), temporal soliton trapping is intrinsically a one-dimensional phenomenon typically observed in optical fibers where diffraction is compensated by the standard fiber guidance mechanism. Temporal solitons were first predicted and observed in single-mode fibers (SMFs). Their applications in digital optical communications have increased due to their capability to behave as nearly ideal bits. Meanwhile, however, the concept of temporal soliton has been considerably generalized by investigating new settings and effects such as polarization, parametric amplification (*see* **Nonlinear Optics, Basics:** $\chi^{(2)}$-Harmonic Generation), gratings (*see* **Fiber Gratings**), stimulated scattering (*see* **Scattering:** Scattering Phenomena in Optical Fibers), and fiber lasers (*see* **Lasers**: Optical Fiber Lasers), etc. Here we briefly review the essential features of these different families of temporal solitons. In particular, in the section on Fiber Temporal Solitons below, we introduce the basic model for fiber solitons, whereas we discuss their application to optical communications in the section on Solitons in Optical Communications below. In the sections on Multi-component Temporal Solitons, and Temporal Solitons in Bragg Gratings below, we introduce significant generalizations of the concept involving

multicomponent and slow-light grating solitons, respectively. Finally, in the section on Solitons on Dissipative nonlinear optics we discuss issues related to solitons in strongly dissipative systems. Note that, throughout the paper, the word soliton is used in the aforementioned general sense, which does not necessarily require the underlying model to be integrable (*see* the section on Fiber Temporal Solitons below,), as implied by the more restrictive and rigorous mathematical meaning of soliton. We further focus our discussion to bell-shaped solitons (for dark solitons, holes on a continuous-wave background, *see* **Solitons:** Optical Fiber Solitons, Physical Origin and Properties), which can be excited by means of standard laser pulses.

Fiber Temporal Solitons

An optical pulse is described by the complex electric-field envelope $E(z,t)$ that modulates the carrier frequency ω_0. Its evolution along the z axis of a silica SMF is described with good approximation by the following universal model for dispersive and weakly nonlinear systems, known as the nonlinear Schrödinger equation (NLSE),

$$\mathrm{i}\frac{\partial E}{\partial z} - \frac{k''}{2}\frac{\partial^2 E}{\partial t^2} + \gamma|E|^2E = 0 \qquad [1]$$

In eqn [1] the second term is responsible for dispersive spreading of pulses ruled by the group-velocity dispersion

$$k' = \left.\frac{\mathrm{d}^2 k}{\mathrm{d}\omega}\right|_{\omega_0}$$

(GVD, known also as chromatic or second-order dispersion), while the first-order dispersion

$$k' = \left.\frac{\mathrm{d}k}{\mathrm{d}\omega}\right|_{\omega_0}$$

has been removed in eqn [1] by introducing the retarded time $t = T - k'z$ measured in the pulse frame traveling at the natural group-velocity $V \equiv k'^{-1}$ of light, T being the physical time in the laboratory frame. The cubic term in eqn [1] is responsible for self-phase modulation (SPM) that stems from the instantaneous optical Kerr effect characterized by the effective coefficient $\gamma = k_0 n_{2I}/A_{\mathrm{eff}} = (\omega_0/cA_{\mathrm{eff}})n_{2I}$, where n_{2I} is the nonlinear index of silica, i.e., the nonlinear refractive index change divided by the intensity which has produced it. The real-world total electric field can be recovered as $\mathcal{E}(z,r,t) = \mathrm{Re}[f(r)E(z,t)\exp(\mathrm{i}k_0 z - \mathrm{i}\omega_0 T)]$, where the transverse modal profile $f(r)$ has been averaged out in eqn [1] to yield an effective fiber area A_{eff}.

The mechanism behind soliton formation can be understood as due to the instantaneous frequency changes along the pulse caused by the Kerr SPM, compensating those due to the group velocity dispersion (GVD) in the anomalous case ($k'' < 0$, at carrier wavelengths longer than 1.3 μm in standard SMFs) where the GVD induces a blue-shift on the pulse leading edge and a red-shift on the pulse trailing edge (in the absence of such compensation the pulse broadens because anomalous GVD means that blue-shifted frequencies travel faster than red-shifted frequencies). Such mechanism of compensation becomes ideal in the case of a soliton waveform. This concept finds its mathematical support in the fact that eqn [1] is a conservative (Hamiltonian) model with the remarkable property to possess infinite conserved quantities, a rather exceptional feature which makes it exactly integrable. Among the solutions, the following fundamental (so-called $N = 1$, see below) bright temporal soliton exists whenever $k'' < 0$:

$$E(z,t) = \frac{1}{\sqrt{\gamma L_{\mathrm{d}}}}\,\mathrm{sech}[\eta(t - \mathrm{d}k'z - t_0)] \times \exp\left[-\mathrm{i}\delta\omega t + \frac{\mathrm{i}}{2}\left(\frac{1}{L_{\mathrm{d}}} + k''\delta\omega^2\right)z + \mathrm{i}\phi_0\right] \qquad [2]$$

where t_0 and ϕ_0 are arbitrary initial position and phase, and $L_{\mathrm{d}} = (k''|\eta^2)^{-1}$ is the characteristic distance after which the GVD causes a significant pulse broadening, the so-called dispersion length. Temporal solitons [2] are characterized by two independent parameters, namely the duration $1/\eta$ and the frequency detuning $\delta\omega$, and possess several remarkable features:

(i) they travel with invariant shape by realizing the condition $N \equiv L_{\mathrm{d}}/L_{\mathrm{nl}} = 1$, i.e., exact balance between the two length scales associated with eqn [1], namely L_{d} and the nonlinear length $L_{\mathrm{nl}} = (\gamma P_1)^{-1}$ associated with the peak power $P_1 = (\gamma L_{\mathrm{d}})^{-1} = |k''|\eta^2/\gamma$ needed for the input pulse [2] to be a soliton;

(ii) in any given fiber with fixed GVD k'' and nonlinearity γ, a larger soliton power P_1 is required for a shorter duration, i.e., narrower solitons are taller;

(iii) solitons experience a phase retardation as a whole (particle), which increases with P_1, i.e., taller solitons have larger shifts;

(iv) as a consequence of Galileian invariance, a frequency shift $\delta\omega$ from ω_0 induces the soliton velocity to change from k'^{-1} to $(k' + \mathrm{d}k')^{-1}$, with $\mathrm{d}k' = \mathrm{d}k''\delta\omega$;

(v) unlike other waves in nonlinear media, collisions between solitons with different velocities are strictly elastic, as shown in the example of Figure 1a; and

(vi) solitons are extremely robust: for instance they can be excited with input peak powers differing from P_1, whereas a weak attenuation α ($\alpha L_\mathrm{d} \ll 1$) induces the soliton to reshape adiabatically, i.e., the peak power decreases, yet the pulse remains locally a soliton by adjusting its width, as displayed in Figure 1b.

More general (and cumbersome) solutions of eqn [1] describe periodic soliton evolutions, such as the interaction of in-phase adjacent input pulses at the same frequency (see Figure 1c), or a single input pulse with sech-shape but peak powers corresponding to higher integer values of N, so-called breathers because of their ability to recover periodically the initial shape after 'breathing' (see Figure 1d for $N = 3$) over the distance $\pi L_\mathrm{d}/2$.

Solitons [2] describe stable propagation-invariant pulses under ideal conditions (lossless case, relatively long pulses and short SMFs). In practical settings, the importance of solitons stems from their robustness against real-world perturbing phenomena described by terms that in turn break the integrability of the underlying model [1]. Situations of this kind arise, for instance, when one accounts for stimulated Raman scattering whose effect is to down-shift continuously the central frequency of ultra-short solitons, or in optical communication systems treated below.

Solitons in Optical Communications

Solitons [2] represent ideal bits for RZ (return-to-zero) optical data sequences. However, fibers have unavoidable losses of about 0.2 dB/km at the usual operating wavelength $\lambda_0 = 1550$ nm. To ensure long-haul connections, the optical signal must be periodically amplified, commonly using erbium-doped fiber amplifiers (EDFAs). The pulse peak power hence

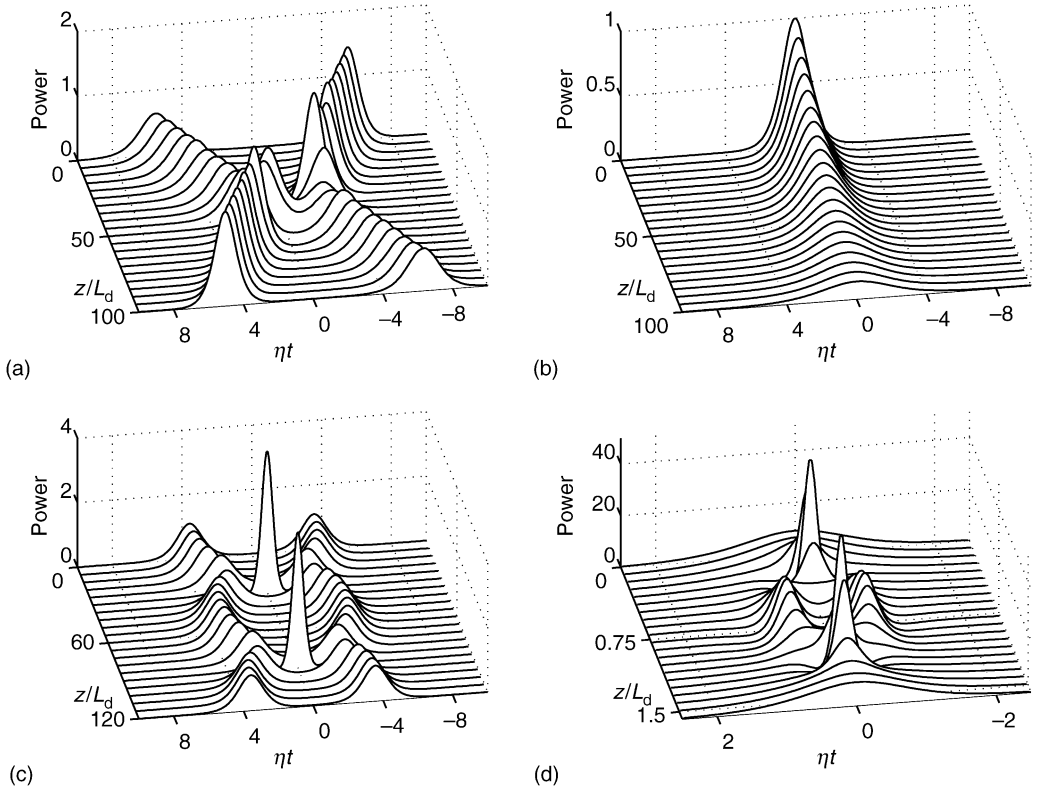

Figure 1 Fundamental features of fiber (NLSE) solitons: (a) elastic collision of two $N = 1$ solitons with different values of parameter pairs (frequency–velocity and amplitude–width); (b) adiabatic soliton damping in the presence of losses; (c) two-soliton bound state (in-phase interacting solitons of equal amplitudes); (d) evolution of a $N = 3$ soliton breather along one period of its evolution. Here the power $|E|^2$ is scaled in units of fundamental soliton power P_1, while distance z and time t are reported in units of L_d and initial pulse-width $1/\eta$, respectively.

undergoes both large exponential decay, because of distributed losses and abrupt lumped amplification under the action of EDFAs. Therefore, the stable local balance between GVD and nonlinearity cannot be rigorously sustained in the fiber. If both losses and amplifiers are accounted for, the mathematical model for pulse envelope propagation along M spans becomes:

$$\mathrm{i}\frac{\partial E}{\partial z} - \frac{k''}{2}\frac{\partial^2 E}{\partial t^2} + \chi|E|^2 E = -\mathrm{i}\alpha E + \mathrm{i}[\exp(\alpha Z_\mathrm{A}) - 1] \times \sum_{n=1}^{M} \delta(z - nZ_\mathrm{A})E(nZ_\mathrm{A}, t) \quad [3]$$

where the RHS contains the perturbing terms arising form distributed losses (α) and lumped amplifications (described by the comb with spacing Z_A).

The analysis of nonintegrable systems, such as eqn [3], can be carried out by appropriate transformations that allow the recovery of a reduced integrable model. The key result is that, under the limitations set by an appropriate length scale, the solitons of the reduced system can be close to those of the original problem. For temporal solitons, such transformation was first called 'the guiding center soliton', envisaging a similarity with the guiding center motion of a charged particle in a magnetic field. The main outcome is that eqn [3] can be reduced to the standard NLSE [1], clearly showing that soliton-like propagation still occurs in the presence of losses (even large, $\alpha L_\mathrm{d} \gg 1$) and rapid periodic amplification. The appropriate scale for these systems is the amplifier spacing Z_A, that must be much shorter than L_d. To reproduce an average behavior similar to the lossless case, it is sufficient to multiply the input condition for an enhancement factor that counteracts the effect of fiber losses. Therefore soliton-like solutions do exist even in fiber systems with loss management, though on average (over several fiber spans) rather than locally.

Another issue that makes solitons suitable as optical bits, lies in their intrinsic aptness to be controlled either through passive or through active systems. Solitons tend to follow their relative center of mass in the temporal or spectral domain. For instance, a powerful technique to overcome one of the major problems, i.e., the growth of noise due to amplified spontaneous emission, may be obtained by deploying periodically along the line optical passband filters. Mollenauer and co-workers have demonstrated that, by sliding the filters progressively (i.e., changing slightly the central peak from filter to filter), one can guide a shape-invariant soliton which adapts its carrier frequency while effectively suppressing the noise. Similar control techniques involve amplitude or phase modulators and a consistent amount of work has focused on the problem of all optical soliton regeneration.

To exploit the idea of soliton in optical communications, however, we should consider the fact that ultra-short optical pulses, suitable for high transmission rates, require extremely low fiber GVD to accomplish the stable balance between dispersion and nonlinearity for a fixed pulse-width and available power. For instance, in order to transmit at 40 Gbit/s, we should achieve a fixed GVD coefficient $D = -(2\pi c/\lambda_0^2)k'' \simeq 0.25$ ps/(km nm) for the whole link.

On the other hand, in many optical systems the fiber nonlinearity is not exploited at all but rather considered as a perturbing effect and a source of penalty that limits the maximum transmission distance. In such an approach the desired cumulated GVD should be as close as possible to zero to avoid errors coming from inter-symbol interference caused by dispersive broadening. Dispersion-shifted fibers may ensure low GVD only in a narrow spectral region, thus limiting the transmission bandwidth. Conversely GVD can be reduced to zero on average, simply combining fiber spans with opposite GVD. The periodic alternance of fiber types may also carry several benefits, e.g., limiting the impact of resonant nonlinear interactions such as four-wave mixing (*see* **Fiber and Guided Wave Optics:** Nonlinear Effects (Basics) for its definition). The different architectures of dispersion management proposed with the twofold scope of limiting nonlinear effects and reducing the cumulated GVD, have immediately stimulated the investigation of their impact on soliton propagation. In the early schemes, the attention was focused on the so-called adiabatic dispersion management, where the GVD was changed proportionally to the soliton power to improve soliton system performances. In contrast with previous works, nonadiabatic map profiles were introduced in the experiments by Suzuki and co-workers to compensate the cumulated dispersion by locating periodically dispersion compensating fibers (DCFs). In net contrast, Doran and co-workers have suggested the use of a combination of fibers with alternate normal and anomalous GVD (i.e., a periodic stepwise variation of GVD), predicting the existence of solitons with a peak power larger than the equivalent classical soliton power, i.e., dispersion-managed solitons (DMSs) The periodic stepwise GVD map is not only conceptually different from earlier designs (with exponentially decaying GVD), but has opened the field to real application due to its simplicity of implementation. The innovative discovery that special pulse waveforms may

propagate in periodically dispersion managed fiber links has triggered the interest of several groups, leading to a complete characterization of the problem, both theoretically and experimentally.

Similar to the case of guiding center solitons, a DMS usually shows a solitonic behavior. However, the DMS has a Gaussian shape surrounded by oscillating tails (see Figure 8 in **Solitons:** Optical Fiber Solitons, Physical Origin and Properties), thus being more suitable, due to its faster decaying tails, to be closely packed in a bit sequence in comparison with a sech-soliton (eqn [2]) of the same FWHM. We show an example of DMS transmission line in the top frame of Figure 2, where we sketched the variation of the GVD of a standard SMF periodically balanced by shorter segments of DCFs with opposite GVD. We report, in the middle frame, the DMS pulsewidth and chirp and in the bottom frame the pulse peak power. As shown, the macroscopic soliton parameters are characterized by large fluctuations: the local minima of pulsewidth correspond to chirp-free points and at such points one observes either a minimum or a maximum of the pulse spectral bandwidth. Nonetheless, all these pulse parameters have periodical evolutions that are fingerprints of an invariant and soliton-like pulse when observed at integer multiples of Z_A. The exact periodicity preserves the pulse waveform and hence the carried information. In DMS transmission we assist at the threefold compensation of energy, GVD and nonlinearity. Similarly to the guiding center solitons, the threefold compensation has an average, rather than pointwise, connotation. However, unlike guiding center solitons, for DMSs the definition of average should take into account the different relevance of pulse peak power in the map. Consequently the nonlinearity is compensated in a weighted manner, and it is not surprising in this context (though astonishing if placed back in the context of the NLSE [1] which requires anomalous GVD), that DMSs have been observed even when the uniform average GVD is weakly normal.

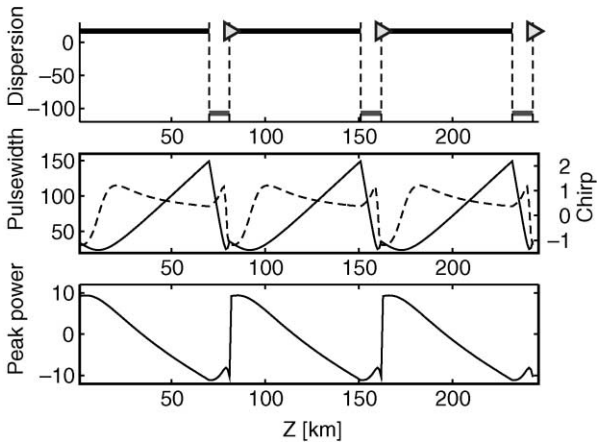

Figure 2 Evolution of soliton parameters along three periods of a fiber link with lumped amplifiers and dispersion management. Top frame: GVD map D(z) [ps/(nm km)] and EDFAs (triangles) location; Middle frame: soliton chirp (in units of 1000 ps^{-2}, dashed line), and pulse-width (in ps, solid line) vs. distance. Bottom frame: DMS peak power (dBm) vs. distance.

The net difference between the local and average GVD allows simultaneous control of different detrimental phenomena: for instance four-wave mixing is reduced by the large local GVD, whereas a small average GVD limits the impact of timing jitter due to amplified spontaneous emission (Gordon–Haus effect). As a result, DMSs perform better than conventional solitons.

Figure 3 shows a typical high-speed (20 Gb/s) single-channel experiment, and the achieved performance in terms of quality factor Q versus propagation distance, with the output after 8100 km. We recall that the Q factor measures the bit-error-rate (an error rate lower than 10^{-9} corresponds to a Q higher than $\sim$ 16 dB). DMSs also allow the control of collisions between solitons that pertain to different channels (we recall that solitons at different carrier frequencies go at different velocities, and hence collide), thus enhancing performances of standard or dense WDM systems.

Multi-Component Temporal Solitons

So far we have discussed temporal solitons described by a single envelope. However, the same mechanism of mutual balance between nonlinearity and dispersion can also be effective for multiple pulses, leading to trap simultaneously multicomponent (or so-called vector) solitons. Solitons of this type are, for instance, those due to the interaction of polarization modes in isotropic or birefringent Kerr media, higher-order modes in large-core (multimode) fibers, or mixing of pulses at different carrier frequencies that interact parametrically (i.e., without net exchange of energy with the medium). The latter case entails a broad class of solitons since virtually any parametric four-photon mixing process in cubic media (e.g., nondegenerate or partially degenerate four-wave mixing, third harmonic generation, ...), or three-photon mixing process in quadratic media (sum- and difference-frequency generation, second-harmonic generation (SHG), optical rectification, etc.) is allowed to sustain them. This opens up the field to an entirely new class of materials, namely noncentrosymmetric (quadratic) materials which usually have stronger nonlinear responses if compared with silica fibers. SHG can be taken as a paradigm to

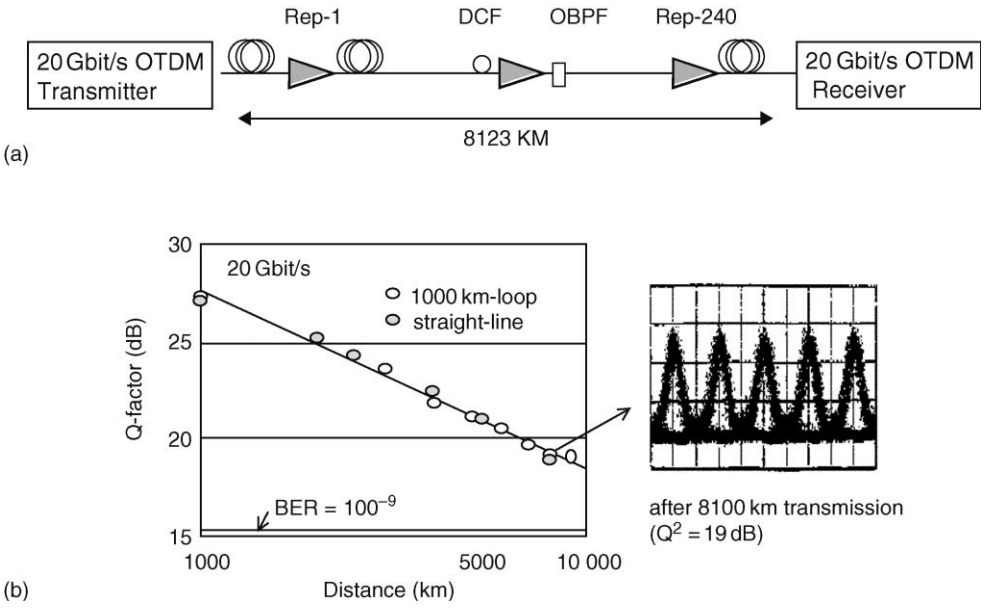

Figure 3 (a) Schematic diagram of the straight-line experiment with optical time-division multiplexing (OTDM) of soliton at 20 Gbit/s; (b) Measured *Q* factor vs. distance comparing experimental results obtained in the straight-line and loop configuration (loop length of 1000 km), respectively. The waveform received after 8100 km is also shown. understand the main features of these multicomponent solitons. In this case, the evolution of the interacting envelopes E_j at carrier frequencies $j\omega_0$, $j = 1, 2$, is ruled by the coupled equations:

$$\left(\mathrm{i}\frac{\partial}{\partial z} - \frac{k_1''}{2}\frac{\partial^2}{\partial t^2}\right)E_1 + \chi E_2 E_1^* \exp(\mathrm{i}\Delta k z) = 0,$$

$$\left(\mathrm{i}\frac{\partial}{\partial z} + \mathrm{i}\delta k'\frac{\partial}{\partial t} - \frac{k_2''}{2}\frac{\partial^2}{\partial t^2}\right)E_2 + \chi E_1^2 \exp(-\mathrm{i}\Delta k z) = 0, \quad [4]$$

where the subscript $j = 1, 2$ indicates that the relative quantities evaluated at frequency $j\omega_0$, $t = T - k'_1 z$, $k''_{1,2}$ are GVD coefficients, $\delta k' \equiv k'_2 - k'_1$ is the group-delay, χ is the effective nonlinear coefficient, and $\Delta k = k_2 - 2k_1$ is the wave-number (or phase) mismatch. In spite of the fact that eqns [4] are not integrable, their stable soliton solutions can be found (numerically) in a wide range of parameters as symbiotic phase-locked pulses $E_{1,2}(z,t)$ that travel undistorted. For instance, SHG solitons exist either in phase-matching ($\Delta k = 0$) or far-off phase-matching (with some limitations for $\Delta k > 0$), and, unlike fiber solitons, also in normally dispersive media ($k''_{1,2} > 0$). As for fiber solitons, their width is related to their peak power, since the basic mechanism is the mutual balance between the dispersive broadening (that depend on the pulsewidth) and nonlinear phase-shifts (that depend on power), which occur due to repeated up-conversion and down-conversion processes, often referred to as cascading. A SHG soliton is robust enough to permit the observation of trapping, even from an input that differs considerably from the soliton (e.g., from the fundamental only), or in the presence of a relatively strong group-delay which tends to rip apart the two-component soliton, inducing walk-off between the two envelopes.

In contrast with fibers, in this case, experiments are necessarily made in relatively short bulk samples, thus resulting in a limited number of dispersion lengths. Usually broad (quasi-planewave) beams are conveniently employed in order to make diffraction ineffective.

The main experimental problem is that, in crystals commonly employed for SHG, the dynamics of typical laser pulses (duration above 100 fs) is fully dominated by the group-delay $\delta k'$. In other words, the material GVD becomes relevant only for pulses as short as a few fs. Therefore, the observation of solitons with longer pulses has been required to tailor the dispersion, which can be accomplished by means of pulses with tilted phase front. As displayed in **Figure 4**, successful compression of 200 fs (FWHM) tilted pulses was observed at relatively large negative Δk in a BBO bulk crystal with effective zero group-delay and enhanced (anomalous) GVD.

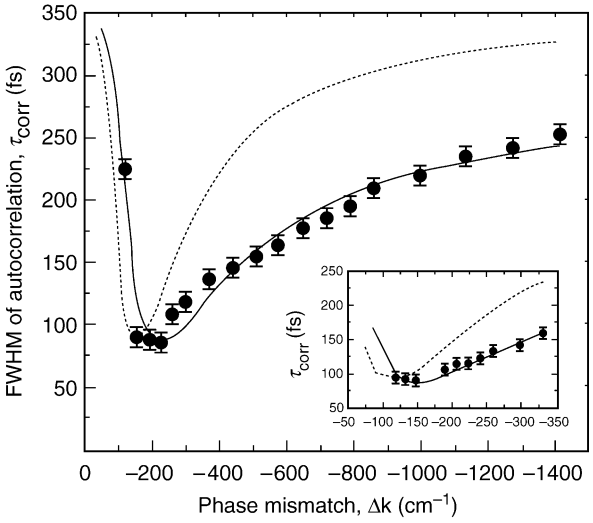

Figure 4 Soliton fomation via SHG: the circles show the output pulse duration (full width at half maximum (FWHM) of autocorrelation τ_{corr}) vs. mismatch Δk, measured after propagation of an input 200 fs tilted pulse (input $\tau_{corr} = 284$ fs) with 13.4 GW/cm^2 peak intensity, in a 7 mm BBO crystal (inset: same with 10.4 GW/cm^2). Superimposed (dotted line) is the corresponding theoretical value obtained from eqn [4]. The solid curve that fits better the data accounts for the additional effect of the material Kerr effect. With permission from Di Trapani P, Caironi D, Valiulis G, Dubietis A, Danielius R and Piskarskas A (1998) Observation of temporal solitons in second-harmonic generation with tilted pulses. *Physical Review Letters* 81: 570–573. © 1998 APS.

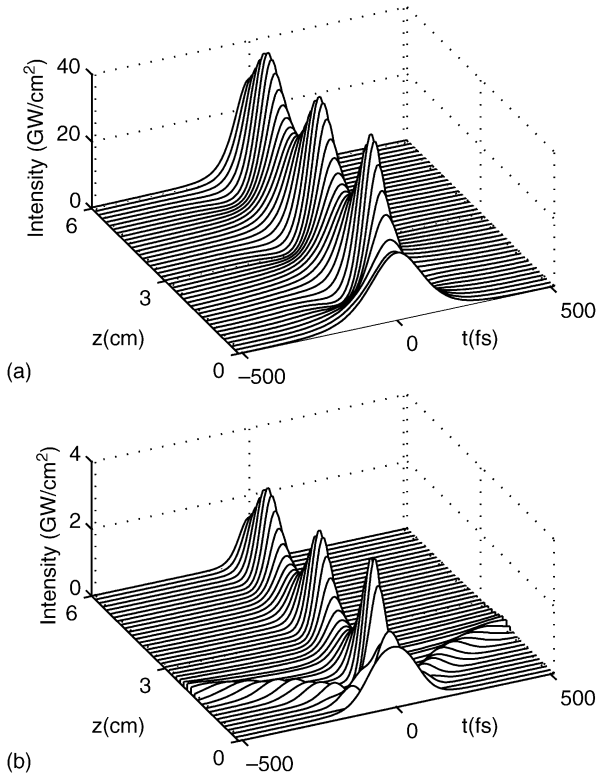

Figure 5 Dynamics of temporal soliton formation ruled by eqn [4]. A compressed soliton is formed via strongly mismatched ($\Delta k = -100$ cm^{-1}) SHG from a 200 fs (FWHM) input pulse at fundamental carrier frequency, in a crystal with $\chi = 1.4 \times 10^{-4}$ W$^{-1/2}$, effective dispersion $\delta k' = 0$ (group–velocity matching) and $k_1'' = -1.8$ ps^2/m, $k_2'' = -0.75$ ps^2/m.

The measured compression is a signature of soliton formation, as clearly indicated by the example of simulated pulse dynamics reported in Figure 5: the pulse at second-harmonic is generated and then trapped with the input one as a two-component bound state. Radiation and oscillations occur, in this case, because the launching conditions (single envelope) are far enough from the two-component soliton.

Temporal Solitons in Bragg Gratings

A linear periodic structure, such as a Bragg grating with pitch Λ, couples counter-propagating waves when their frequency lies close to the Bragg frequency ω_B (vacuum wavelength $\lambda_B = 2n_0\Lambda$) defined by the resonance condition $k(\omega_B) = \pi/\Lambda$. Such a type of structure supports a different type of temporal solitons, so-called gap solitons (GSs) since they originate from a linear dispersion relationship of the type shown in Figure 6a, characterized by a stop-band (gap) centered around ωB. The gap is characterized by a unitary grating reflectivity, as shown in Figure 6b, and the forward linear propagation is therefore forbidden. However, if the incoming wave is intense enough to induce the refractive index to increase through the optical Kerr effect, the Bragg resonance (and the whole gap) is shifted downwards (in frequency) allowing for self-transparency at the operating frequency. GSs can be understood as bell-shaped envelopes which are allowed to travel along the grating due to a high-intensity core that bleaches the reflectivity, while the high reflectivity seen by the tails takes the pulse together. GSs are expected to be slow because the slope of the dispersion curve tends to zero when approaching the gap, while its curvature results in the grating GVD (huge if compared with material GVD in real-world units), which is exactly balanced by the nonlinearity when the GS is formed. This naive portrait is supported by a more thorough analysis starting from the coupled-mode equations obeyed by the forward $E_+(z,T)$ and backward $E_-(z,T)$ envelopes at frequency ω_B, propagating along a (e.g., fiber) Bragg grating with Kerr effect (inducing SPM and

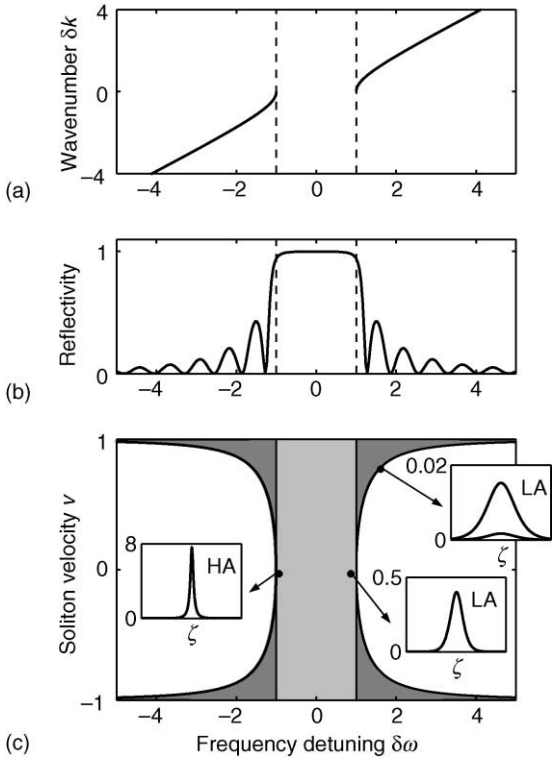

Figure 6 (a) Bragg linear dispersion relationship in normalized (dimensionless) units: wave-number shift $\delta k = (k(\omega) - \pi/\Lambda)/\Gamma$ vs. frequency detuning $\delta\omega = k'(\omega - \omega_B)/\Gamma$; (b) linear grating reflectivity vs. $\delta\omega$ for a grating figure of merit $\Gamma L = 4$; (c) existence domain (whole shaded area) of GSs in the normalized detuning–velocity plane ($\delta\omega, \nu \equiv k V_{sol}$). The light shaded area corresponds to the stop-band $|\delta\omega| < 1$ (inner region between dashed lines in a–b). The insets show samples of GS intensity profiles vs. the moving frame coordinate $\zeta = (1 - v^2)(z - V_{sol} T)$. Zero-velocity GSs have symmetric envelopes ($|E_+| = |E_-|$) and range from high-amplitude (HA) to low-amplitude (LA) across the gap. The third inset shows a moving GS in the experimentally accessible region, where it retains LA but has a stronger component in the direction of motion.

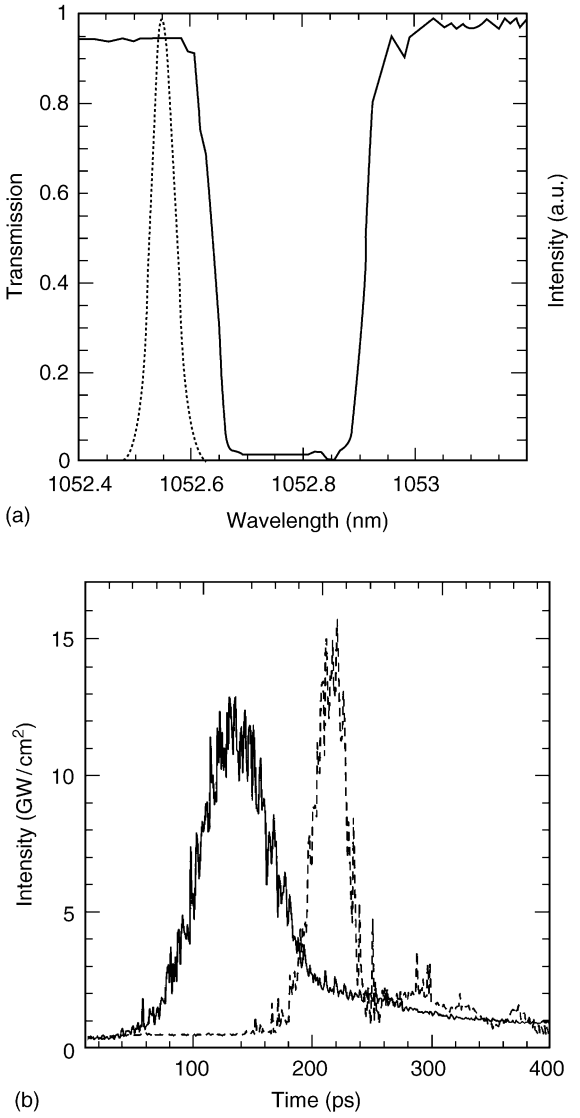

Figure 7 Gap solitons in a fiber Bragg grating: (a) measured pulse spectrum compared with the linear grating transmission, (b) compressed (15 ps) and delayed pulse transmitted at high intensity (dashed line), compared with the pulse transmitted at frequency far from the Bragg resonance (solid line) where it retains its input width of 80 ps. cross-phase modulation):

$$i\left(k'\frac{\partial E_\pm}{\partial T} \pm \frac{\partial E_\pm}{\partial z}\right) + \Gamma E_\mp + \gamma(|E_\pm|^2 + 2|E_\mp|^2)E_\pm = 0 \quad [5]$$

The linear dispersion associated with eqn [5] is as in Figure 6a, with a stop-band $|\omega - \omega_B| \le \Gamma/k'$ proportional to the index corrugation depth through the Bragg coupling coefficient Γ. In the nonlinear regime, GS solutions of eqn [5] differ qualitatively from conventional fiber solitons [2]:

(i) first, GSs are indeed slow since the two envelopes can travel locked with any soliton velocity V_{sol} such that $|v| \equiv |k' V_{sol}| \le 1$, i.e., lower than the natural group velocity k'^{-1};

(ii) GSs exist only in a narrow bandwidth, i.e., the shaded area in Figure 6c, which corresponds to the gap seen in the soliton frame (it reduces to the conventional stop-band for still solitons and gets wider for faster GSs); and

(iii) the gap is strongly asymmetric since lower intensity is required to induce transparency close to the high-frequency band-edge where, as a consequence, GSs have low amplitudes and

are stable (the amplitude grows moving towards the low-frequency bandedge, where GSs become unstable).

Experimentally, GSs have been typically observed with pulses at frequency close to the blue bandedge of fibers (see **Figure 7a**) and AlGaAs waveguides with built-in Bragg gratings of a few centimeters. The typical signature of GSs, illustrated in **Figure 7b**, is the enhanced pulse transmission observed under the operating conditions of **Figure 7a** when the input intensity is sufficiently high. The transmitted pulse experiences pulse compression and a significant group-delay (measured with respect to the transit-time at frequency far off the stop-band), witnessing its nature of slow-light solitons.

Finally, we emphasize that grating solitons can also be supported in the case where the two modal envelopes propagate in the forward direction along a grating whose period Λ is long enough to be resonant with the modal phase slippage, thus inducing efficient linear coupling between them. In this case, the structure has a gap in wave-number, and solitons are slow in the frame traveling at the average modal group-velocity. Soliton formation is expected to lead to grating-induced compensation of the group-delay between the modes. Experiments on such types of structures have been carried out only recently.

Solitons in Dissipative Nonlinear Optics

Temporal solitons can also be observed in nonlinear optical interactions that involve changes of the state (energy level) of matter as in inverted media or scattering phenomena. For instance, early studies in the 1960s have demonstrated that coherent pulses with energy above a critical level can pass through resonant (two-level) atoms without being absorbed, a phenomenon denoted as self-induced transparency. Such pulses are temporal solitons solutions of the Maxwell–Bloch model which describes the atom–light interaction.

Also scattering phenomena occurring in optical fibers, such as Raman and Brilluoin scattering, possess three-wave solitons, in which the pump and scattered (Stokes) light waves are coupled to a phonon field of the acoustic or optical branch (for Brillouin or Raman, respectively).

Perhaps more important from the point of view of the modern applications, are fiber lasers composed by spans of active and/or passive fiber closed to form a recirculating loop. These types of structures can often be described by distributed (averaged over several round-trips) models, which take the form of a dissipative perturbed NLSE, known as the Ginzburg–Landau equation (GLE):

$$i\frac{\partial E}{\partial z} - \frac{k''}{2}\frac{\partial^2 E}{\partial t^2} + \chi|E|^2E = igE + ig_{nl}|E|^2E + iq|E|^4E + \frac{i}{\Omega_f^2}\frac{\partial^2 E}{\partial t^2} \quad [6]$$

where g is the excess (net) gain ($g > 0$) or loss ($g < 0$), g_{nl} and q describe the nonlinear gain mechanism and its saturation (usually introduced to control the mode-locking), and Ω_f is linked to spectral filtering. Several soliton (pulse) solutions of the GLE [6] can be found even when the parameters (g, g_{nl}, q, Ω_f) are such as to constitute a strong perturbation of the NLSE. Unlike NLSE solitons [2], pulse solutions of the GLE [6] are usually chirped (i.e., possess a nonlinear phase profile), and have fixed amplitude for a given value of the parameters. The set of soliton waveforms is generally richer and includes, for instance, flat-top stationary pulses, two-pulse bound-states, solitons moving at fixed velocity, etc. Although instabilities of the background (for $g > 0$) or of the pulse itself can affect their observability, large islands of stability in the parameter space can be found. The relevant role of stable solitons in mode-locking and intra-cavity pulse formation mechanisms has been demonstrated in many different fiber laser geometries, for which we refer the reader to the more specialized papers listed as Further Reading at the end of this article. We point out that some schemes, for instance the stretched pulse-fiber laser developed at MIT, involve a basic configuration (alternating GVD within the cavity length) which is quite similar to that seen in the framework of DMSs, thus exhibiting the same basic physical mechanism (strong compression and stretching of the pulse along each round-trip which play the role of the map period for a DMS).

List of Units and Nomenclature

BBO	β-barium borate
DCF	dispersion compensating fiber
DMS	disperion managed soliton
EDFA	Erbium doped fiber amplifier
GLE	Ginzburg–Landau equation
GS	gap soliton
GVD	group-velocity dispersion
NLSE	nonlinear Schrödinger equation
OTDM	optical time-division multiplexing
SHG	second-harmonic generation

SPM self-phase modulation
WDM wavelength division multiplexing
Amplifier spacing L_A [m]
Bragg frequency ω_B [Hz]
Bragg period Λ [m]
Central wavelength λ_0 [nm]
Coupling coefficient Γ [m^{-1}]
Dispersion coefficient D [ps nm^{-1} km^{-1}]
Dispersion length L_d [m]
Effective area A_{eff} [m^2]
First-order dispersion k' [s/m]
Fundamental soliton power P_1 [W]
Gain (linear) g [m^{-1}]
Gain (nonlinear) g_{nl} [m^{-1}]
Group-delay δ [s/m]
Group-velocity $V = k'^{-1}$ [m/s]
Group velocity dispersion k'' [ps^2 m^{-1}]
Inverse pulse-width η [s^{-1}]
Light velocity in vacuum c [m/s]
Loss coefficient α [m^{-1}]
Nonlinear coefficient (fiber) γ [m^{-1} W^{-1}]
Nonlinear coefficient (quadratic bulk materials) χ [$W^{-1/2}$]
Nonlinear refractive index n_{2I} [m^2 W^{-1}]
Nonlinear length L_{nl} [m]
Refractive index (linear) n_0
Retarded time (in the moving frame) t [s]
Spectral filtering coefficient Ω_f [Hz $m^{1/2}$]
Time in the laboratory frame T [s]
Wave-number mismatch Δk [m^{-1}]

Introduction

Visible light occupies a portion of the electromagnetic spectrum between frequencies of approximately 400 terahertz (THz) to 750 THz, where 1 THz is 10^{12} oscillations per second. Optical radiation, which includes adjacent infrared and ultraviolet portions of the spectrum, covers a frequency range of approximately 15–1500 THz. The techniques required for measuring frequencies in this range are qualitatively different from those currently employed in the radio frequency (RF) and microwave portions of the spectrum, where high-speed electronic counters make a direct measurement possible.

The frequency of an oscillatory phenomenon is the number of oscillations that occurs in unit time, or alternatively, the inverse of the period of one oscillation. Thus, to understand frequency, we must understand time, which is intrinsically related to phase. Only a time interval, the time elapsed between two events, has fundamental physical meaning. The 'time' that we are most familiar with, the time of day (including the date), is based on an arbitrarily chosen starting point. The starting point chosen in current international agreements can be traced to noon on December 31st, 1899. Furthermore, the time defined by those agreements, Universal Coordinated Time (UTC), is periodically adjusted relative to atomic time (discussed below) to compensate for irregularities in the rotation of the Earth.

Knowledge of the transition frequencies (energies) in simple atoms gives detailed information on the structure of the atoms. This can be used to test our understanding of the fundamental interactions in nature by comparing the measured frequencies with predictions of fundamental physical theories, in this case quantum electrodynamics (QED). Beautiful results along these lines are exemplified by precision measurements of transition frequencies in hydrogen and helium. In addition, the ability to measure and precisely control laser frequencies promises tremendous advances in the performance of the next generation of atomic clocks and frequency standards. These have potential applications to navigation and communication systems.

The measurement of frequency and time intervals also involves a choice, that of the unit of time, i.e., the definition of the second. The original definition of the second was based on the rotation of the Earth. However, not only is it irregular, but it is slowing down. Both of these facts limit its utility as a frequency standard. Once atomic clocks were highly developed, the second was redefined in 1967 to be the time it takes for the $F = 4$, $m_F = 0 \rightarrow F = 3$, $m_F = 0$ transition in the hyperfine structure of the ground state of ^{133}Cs to undergo 9192 631 770 oscillations. Thus an 'absolute' measurement of time interval, and hence frequency, must be directly connected to this defining frequency. The basic structure of an atomic clock is shown in Figure 1.

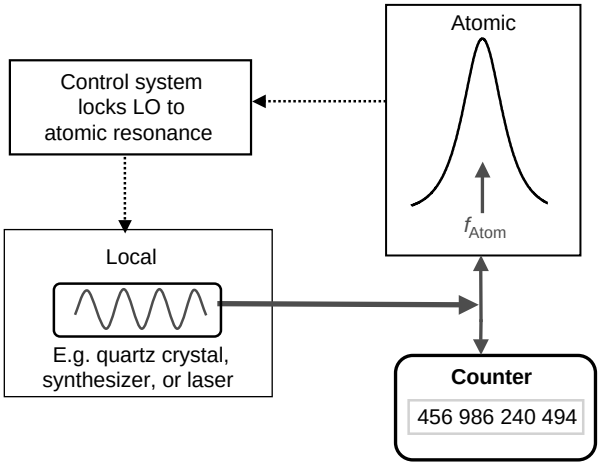

Figure 1 An atomic clock has three basic components: an atomic resonance, an oscillator to probe and lock to the atomic resonance, and a counter that records the number of oscillations and thus displays the time interval since some chosen starting time.

Frequency standards (or clocks) are characterized by three properties: accuracy, stability, and reproducibility. Accuracy describes how well the natural and fundamental atomic frequency is produced by the atomic frequency standard. Stability describes the frequency fluctuations on short timescales (an accurate but unstable standard produces a frequency that fluctuates around a constant mean that is the atomic frequency). Reproducibility between standards addresses whether or not two implementations of the standard produce exactly the same frequency. Atomic clocks are intrinsically accurate because the frequency of the transitions they are based on is determined by identical atoms in nature. The largest inaccuracies are usually due to environmental perturbations such as tiny variations in the local magnetic field.

A careful analysis of all of these issues, together with technical considerations, yielded the choice of cesium for the current definition of the second. Other common frequency standards include quartz crystal oscillators, hydrogen masers, and rubidium vapor cell standards. Quartz oscillators are inexpensive and have good stability, but in comparison to atomic standards they suffer from accuracy and reproducibility issues. Hydrogen masers have the best stability, but also poor accuracy and reproducibility compared to cesium. Vapor cell rubidium standards can be small and inexpensive but have poorer accuracy than cesium beam standards due to cell and buffer gas effects.

There are several motivations for using optical sources rather than RF or microwaves to measure time intervals and frequencies. Obviously, a higher oscillation frequency can divide time into smaller units and this can provide higher measurement precision. It is thus natural to use the highest oscillation frequency that can be precisely counted to measure time and frequency. Not long after lasers were invented, suggestions were made that it would be possible to make optical frequency standards using lasers locked to narrow atomic resonances.

A basic feature of optical transitions is that they have a very high Q factor (the ratio of the center frequency to the linewidth). This allows them to be measured to very high precision (current measurements are good to a few parts in 10^{15}). It may be possible to use this high precision to build improved atomic clocks that use optical transitions instead of the microwave transition currently being used. Candidates for optical standards include both trapped ions (Hg^+, Yb^+, Sr^+, and In^+ are under investigation) and laser-cooled neutral atoms (Ca, Sr, Mg, Ba, and Ag). The high precision is also utilized for fundamental tests of quantum electrodynamics by comparing transition frequencies (usually of hydrogen or helium atoms) to first-principle calculations. For comparison Figure 2 shows the relevant transitions and energy levels in the Cs microwave standard and the Hg^+ optical frequency. It is even possible to use the precision of atomic clocks for high-sensitivity tests of variation in the fundamental constants with time. Finally, because the speed of light is constant length measurements based on the wavelength of light with a known frequency, the precision of length metrology ultimately rests on optical frequency metrology.

An obvious question, which might occur to many in the field of optics, is why a standard spectrometer does not provide absolute frequency measurements. All spectrometers measure wavelength, not frequency, based on interference between light traveling two different path lengths. Thus, knowledge of the path length is needed to determine the wavelength. However, since length is now defined using the speed of light, the definitions become circular unless a source of light with known absolute frequency is available. In addition, frequency measurement is intrinsically more precise and reliable than mechanical length measurement.

Recently, there has been a significant breakthrough in optical-frequency metrology and optical clocks by using mode-locked lasers that generate optical pulses with durations of a few femtoseconds. Before discussing optical frequency metrology based on mode-locked lasers, we will review earlier techniques to provide the necessary background. After describing

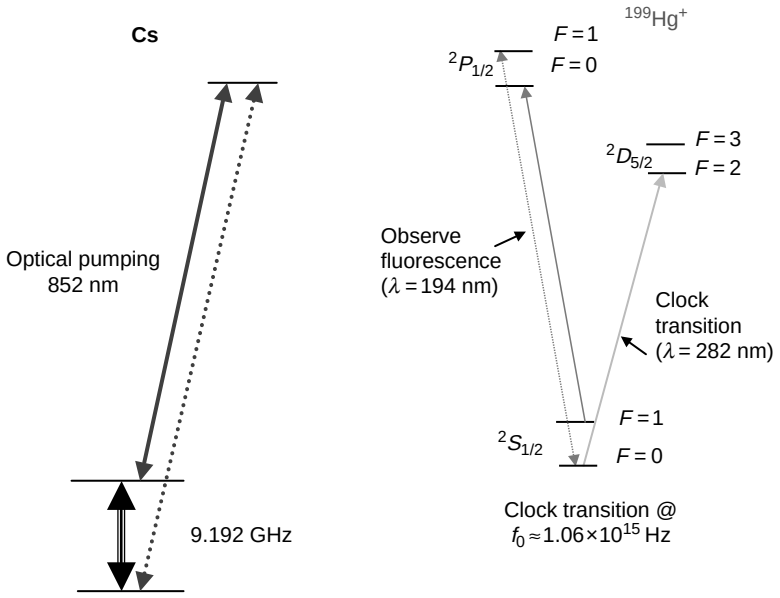

Figure 2 Simplified energy level diagram of Hg^+ and Cs.

methods that use mode-locked lasers, we will then provide a summary of current measurements and standards. Finally we will briefly describe the outlook for the future of absolute optical frequency metrology.

Background

To imagine being able to measure the frequency of light we need to have laser sources with high coherence, like that of radio waves, where the phase is stable enough to be measured. Even though the first beat-note between two lasers was demonstrated in the 1960s, most lasers were not coherent (stable) enough that the optical phase could be tracked for much longer than about 10 to 100 ns. After many years of research and inspiring technological achievements, Hall, Chebotayev, Bergquist and others were able to stabilize the frequency of tunable laser sources to the point that lasers could indeed be considered coherent sources, with the phase continuously measurable and even predictable for times as long as seconds. Once the lasers were stable enough to be counted, there was still the essential problem that no counter was fast enough to actually count optical frequencies.

With spectrally pure laser sources it was possible to conceive of measuring optical frequencies by extending the nonlinear methods that are used to generate and measure RF and microwave frequencies. By using simple nonlinear components such as diodes, it is easy to generate high harmonics of an input frequency in the RF and microwave regions of the spectrum. At least in principle, and by direct analogy, it seemed that it should be possible to multiply coherent sine waves from radio frequencies up through the microwave region to reach the THz frequencies of far-infrared lasers, and then to use nonlinear optical methods to multiply on up to the infrared (IR) and eventually to the visible region of the spectrum. The concept is simple enough, $f \rightarrow 100 \times f \rightarrow 1000 \times f \rightarrow 2000 \times f \rightarrow 4000 \times f \ldots$ until you reach an optical frequency. Multiplication up to the microwave region works quite well, but unfortunately the nonlinear optical processes in the far-infrared, IR, and optical regions are typically quite inefficient; the power at the second harmonic is typically only 10^{-5} times the square of the fundamental power in watts. Just multiplying a single-frequency laser by a factor of two can be a technological challenge. After reaching a microwave frequency of about 50 GHz we still require a multiplication factor of 10^4 to reach the visible at 500 THz. Since we are usually forced to multiply in the IR and optical by factors of 2, we have $2^N = 10^4$, which means we require $N \approx 13$ multiplication stages. This is approximately the number of stabilized laser oscillators that are required to span the frequency gap from the microwave to the visible. Notwithstanding these technological limitations, Evenson and collaborators did a groundbreaking demonstration of a harmonic frequency chain in 1972 that connected a microwave atomic frequency standard and a stabilized HeNe laser in the IR at 88 THz. With a concerted multiperson effort, more lasers, and 10 years of research, Jennings and co-workers finally succeeded in extending the harmonic optical frequency chain to the visible. That original optical frequency chain from the RF to the

visible is diagramed in Figure 3. In the succeeding 18 years, only three other harmonic frequency chains were built world-wide that connected the microwave standards to optical frequencies.

An alternative scheme for measuring optical frequencies is the optical bisection method, a conceptually simple technique proposed by Telle, Meschede and Hänsch, for dividing down from

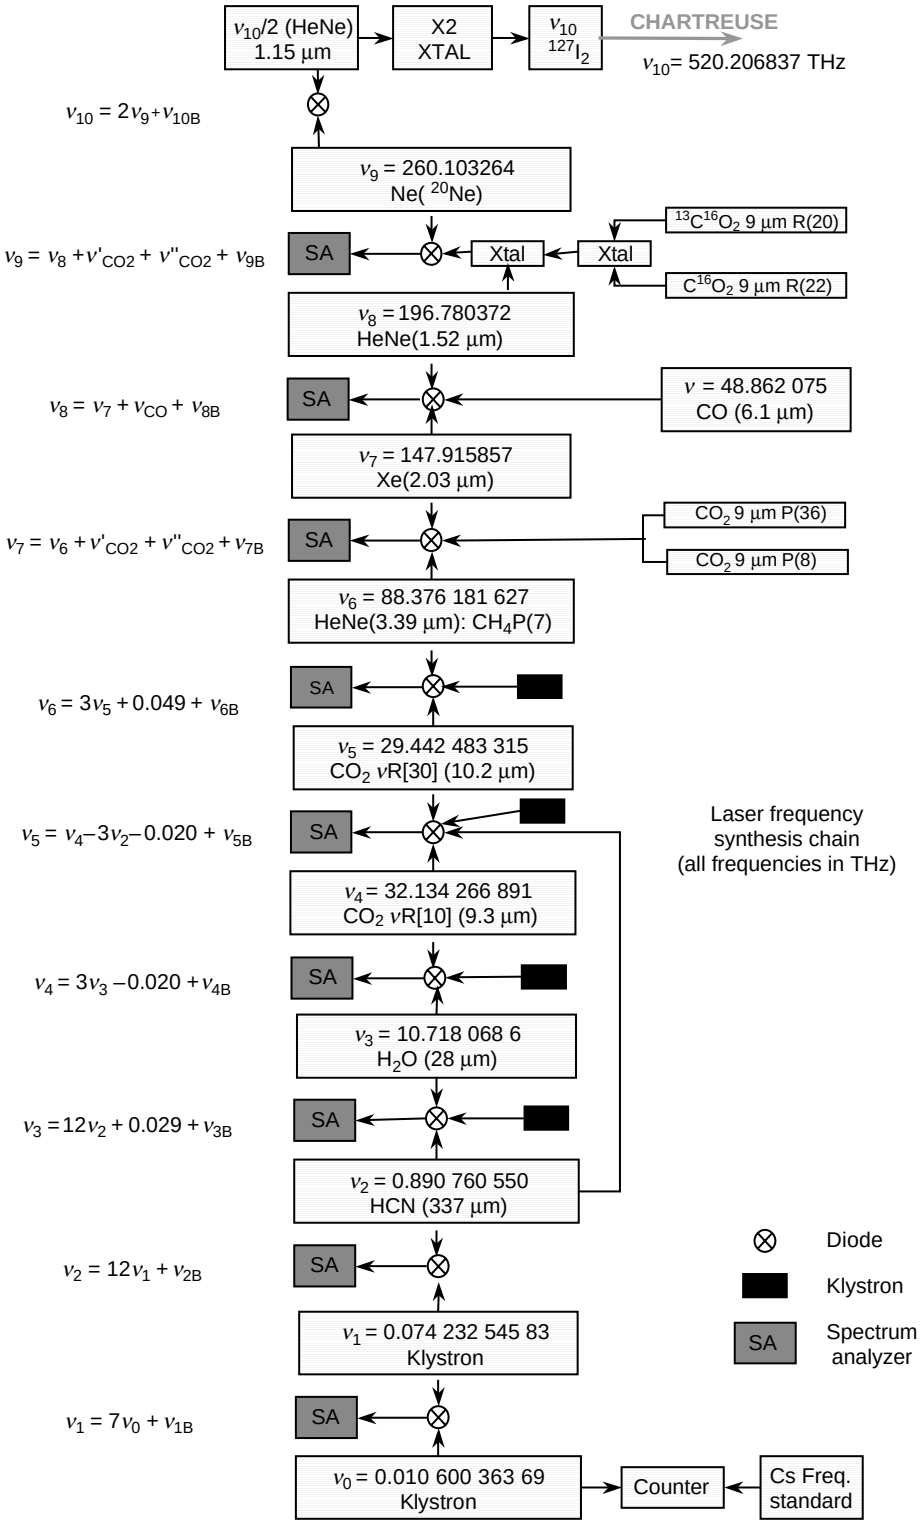

Figure 3 Schematic of the first frequency chain used to measure optical frequencies relative to the Cs standard.

optical frequencies to microwaves. In fact, the bisection method divides an arbitrary optical frequency interval in half by utilizing second-harmonic generation and sum-frequency-mixing, and forcing the condition that $2f_3 = f_1 + f_2$. Thus, the laser at frequency $f_3 = (f_1 + f_2)/2$ bisects the frequency interval between the lasers at f_1 and f_2. The optical bisection method has the following two significant advantages over the multiplication method: the phase noise is decreased in successive divisions (rather than increased by multiplications), and the system could be constructed out of one convenient and reproducible laser technology, say diode lasers in the near-visible. In principle, any optical frequency could be measured by successive operations of the optical bisector. Optical frequency intervals as large as 8 THz have been measured with this method, but even though it is feasible, no bisection system has been built to date that connects the optical region all the way to countable microwave frequencies. The main limitation is the same as that facing the multiplication scheme: it still requires lots of stabilized laser sources to divide by factors of 2 from 10^{15} to 5×10^{10} Hz. The problem can be reduced somewhat by taking advantage of an optical-frequency comb generator based on an electro-optic modulator inside a resonant optical cavity. These systems, developed by Korougi and others, generate many coherent microwave sidebands on a laser so that optical frequency intervals on the order of 5 THz can be measured.

Even combining all of these ideas and techniques, a convenient system to count optical frequencies remained elusive. This has now changed with the revolutionary new optical frequency combs based on mode-locked femtosecond lasers.

Optical Frequency Metrology with Femtosecond Combs

Recently, the introduction of mode-locked lasers into the field of absolute optical frequency metrology has resulted in an important advance. The extremely complex frequency chains described above can be replaced by a single mode-locked laser if it produces pulses with sufficiently large bandwidth. Although the underlying ideas are not new (they were originally discussed by Hänsch and Chebotayaev in the 1970s) it is only recently that mode-locked lasers with the required characteristics were developed and the concept carefully tested.

The dramatic simplification of a frequency chain that uses a mode-locked laser means that absolute optical-frequency measurements can now be made by a single person as compared to the team of approximately 10 highly trained scientists required to run the previous chains. This has resulted in a large number of measurements being reported in the last 2 years. The simplicity also allows longer averaging times and a greater number of measurements to be used in determining the final reported frequency. In addition, since a simpler system has fewer sources of error, it has improved the quality of measurements made in a given amount of time.

Mode-locked lasers produce ultrashort pulses of light. For a typical modern high-quality mode-locked laser, the pulse duration is around 10 fs (1 fs $= 10^{-15}$ second), corresponding to three or four optical cycles in the near-infrared, where these lasers typically operate. The current best mode-locked lasers can produce pulses that are shorter than two optical cycles in duration (5–6 fs). Since the spectrum of these lasers is complicated, the bandwidth is significantly larger than it would be for a smooth pulse such as one with a Gaussian or hyperbolic-secant temporal intensity profile.

At first sight, using mode-locked lasers for optical-frequency metrology seems counter-intuitive, because optical-frequency metrology clearly requires very well-defined frequencies in contrast to the broad frequency spectrum of ultrashort pulses. This apparent conundrum is resolved by the fact that a mode-locked laser actually produces a very regularly spaced train of ultrashort pulses. The ultrashort pulses emitted by a mode-locked laser are replicas of a steady-state pulse that circulates inside the cavity of the laser. Every time the internal pulse impinges on the output coupler, which is a partially reflective mirror, a portion of it is transmitted, producing the output. The timing between these output pulses is determined purely by the time, τ_c, for the intracavity pulse to make one round trip, which is typically between 1 and 20 ns. The spectrum of a train of pulses is a regularly spaced 'comb' of frequencies spaced by the repetition rate of the train, $f_{rep} = 1/\tau_c$. If all of the pulses are identical, then these comb lines are just integer multiples of f_{rep}. However, due to dispersion, the group and phase velocities are different inside the cavity of a mode-locked laser. This leads to a pulse-to-pulse shift in the phase between the carrier and envelope (which we call the carrier–envelope phase; ϕ_{ce}, the pulse-to-pulse shift of ϕ_{ce} is designated by $\Delta\phi_{ce}$). The presence of $\Delta\phi_{ce}$ results in a rigid shift of all the comb lines by an amount $\delta = 2\pi\Delta\phi_{ce}/f_{rep}$. Thus the frequencies of the comb lines are given by $\nu_n = nf_{rep} + \delta$, where n is a large integer of order 10^6. The essential point of this equation is that it gives optical frequencies in terms of RF frequencies (f_{rep} and δ) that can easily be measured with conventional electronics and

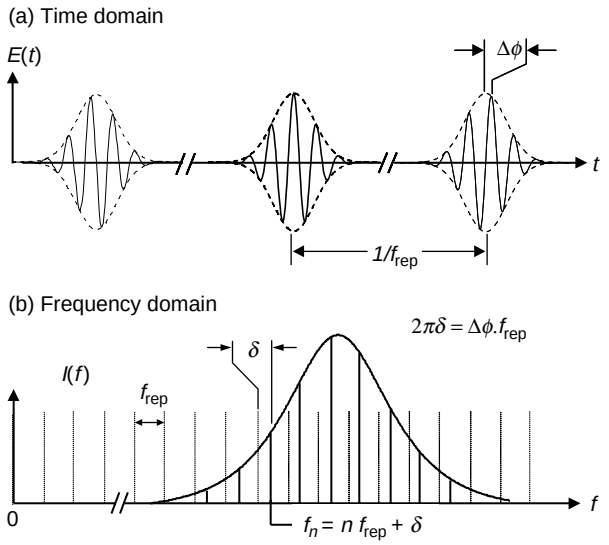

Figure 4 Time–frequency correspondence and relationship between $\Delta\phi$ and δ. (a) In the time domain, the relative phase between the carrier and the envelope evolves from pulse to pulse by the amount $\Delta\phi$. (b) In the frequency domain, the elements of the frequency comb of a mode-locked pulse train are spaced by f_{rep}. The entire comb is offset from integer multiples of f_{rep} by an offset frequency $\delta = \Delta\phi f_{rep}/2\pi$.

compared to the microwave cesium frequency standard. The relationship between the time and frequency domains is shown in Figure 4.

Given such a comb of frequencies, a heterodyne measurement readily yields the frequency difference between the unknown optical frequency of a narrow-band source (typically a single frequency laser) and the optical frequency of a nearby comb line. Thus, the absolute unknown frequency can be determined if the absolute frequencies of the comb lines are known. This requires measurement of f_{rep} and δ. The repetition rate, f_{rep}, is easily measured with a fast photodiode. Measurement of δ requires somewhat greater effort.

The development of a 'self-referencing' method to easily measure δ is the key enabling breakthrough that has brought about the recent revolution in optical-frequency metrology. It is called self-referencing because it provides a direct measure of δ with no other optical frequencies as input. It works by comparing frequencies that differ by a factor of two (typically these lie in the wings of the spectrum) using second-harmonic generation. Specifically, the frequency difference between the second harmonic of a comb line n and the comb line $2n$ is given by $2f_n - f_{2n} = 2(nf_{rep} - \delta) - (2nf_{rep} - \delta) = \delta$. Such a frequency difference is easily measured using a heterodyne beat. This technique is shown schematically in Figure 5. Other variations on this basic idea are possible; for example, rather than frequency doubling

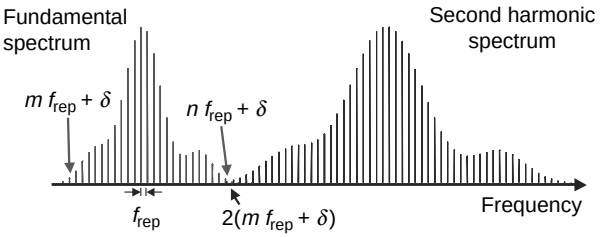

Figure 5 Schematic of the self-referencing technique for determining the offset frequency of the frequency comb produced by a femtosecond mode-locked laser. The frequency difference between the fundamental comb and its second harmonic is the offset frequency. In the region where overlap occurs, this is easily detected as a heterodyne beat.

the comb itself, it is also possible to extract the same information by comparing the comb lines to a single-frequency laser and its second harmonic.

Implementation of the self-referencing technique requires a pulse spectrum that spans a factor of two in frequency (an optical octave). Although a laser has recently been demonstrated that produces such a broad spectrum, they are not commonly available. However, the development of microstructured fiber has made it easy to broaden the spectrum of ordinary mode-locked lasers so that it spans an octave, as was first demonstrated by Ranka and co-workers at Bell Labs. The broadening occurs because optical nonlinearity in the fiber results in self-phase modulation of the laser pulse. Microstructure fiber achieves guiding by surrounding the core region with microscopic air holes, as compared to regular fiber that uses doping to produce a difference in the index of refraction. The much larger difference in the index of refraction in microstructure fiber allows a smaller core region to be used, which increases the effective nonlinearity. It also makes it possible to modify the dispersion such that the group velocity dispersion goes through zero for light with a wavelength close to 800 nm. This is crucial because group-velocity dispersion in ordinary fiber causes ultrashort pulses to temporally spread, which lowers the peak power and hence nonlinearity. It is possible to implement self-referencing techniques using less bandwidth if higher orders of nonlinearity are used; for example, if the difference between the second harmonic of the high-frequency end and third harmonic of the low-frequency end of the comb are used, only a half-octave bandwidth is required.

Given the ability to measure both f_{rep} and δ, and as long as its frequency lies within the comb spectrum, it is possible to measure the optical frequency of any optical source by measuring the heterodyne beat

with a nearby comb line. Thus, an absolute optical frequency measurement comes down to measuring three RF frequencies. It is often advantageous to actively control either one or both of f_{rep} and δ to hold them to a fixed frequency. This requires real-time adjustment of some parameters of the mode-locked laser to affect the necessary feedback. Controlling f_{rep} is straightforward; it is achieved by simply changing the cavity length of the laser, typically by mounting a mirror on a piezoelectric transducer. Controlling δ is more challenging, as it requires a differential change between the cavity group delay and phase delay. This has been achieved by adjusting the pump power, which in turn controls the energy of the intracavity pulse, and/or by tilting the end mirror of the cavity in lasers that employ prism dispersion compensators. Since the optical spectrum is spread out across this mirror, tilting it can be thought of as a frequency-dependent change in the cavity length, with the optical frequency corresponding to the pivot point of the tilt experiencing no length change, while those on opposite sides of the pivot point see changes with opposite signs.

In addition to the three RF frequencies, it is necessary to know the large integer n that describes the comb line that is beat against the unknown source. If a priori knowledge about the unknown source is available with precision somewhat better than $f_{rep}/2$ or better, n can readily be determined. For typical mode-locked lasers, standard commercial wavemeters can provide this level of precision. In the absence of additional outside information, n can also be determined with some effort and precision measurements by changing f_{rep} and δ in a systematic fashion. In the end, the simple formula $f_n = nf_{rep} + \delta$ gives the optical frequency of any arbitrary nth mode of the femtosecond optical comb. With this established, the frequency of any single-mode laser within the octave span of the comb can be determined simply by measuring the frequency of the beat-note generated in a photodiode between the cw laser and the known frequencies of the comb.

The diagram in Figure 6 shows how a femtosecond comb acts as an optical frequency synthesizer, which provides frequencies that are known relative to the input frequency (provided by a hydrogen maser in the figure). A typical series of measurements is shown in Figure 7 for the NIST Hg^+ single ion standard. The inset shows the results of numerous measurements for the frequency of Hg^+ relative to the NIST primary cesium standard.

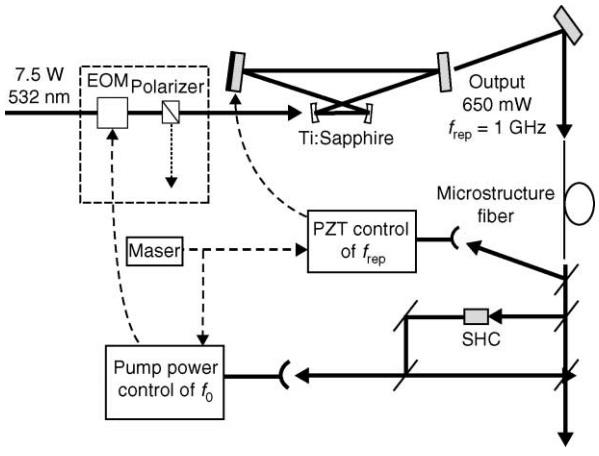

Figure 6 Schematic example of how the femtosecond comb is configured to make optical frequency measurements relative to the reference frequency provided by a hydrogen maser (Maser) that is in turn calibrated to a cesium atomic frequency standard. The repetition rate of the pulses from the Ti:Sapphire laser are detected in a photodiode and are controlled using a piezoelectric transducer (PZT) that changes the length of the laser cavity. The microstructure fiber and second harmonic crystal (SHC), provide the 'self-referencing' beat-note signal that is used to control the offset frequency, δ, by changing the power of the pump laser with an electro-optic modulator (EOM). This 'self-referenced' system then provides a set of modes with known frequencies spanning the visible. An unknown laser frequency can then be measured by making a beat-note with one of the modes of the comb.

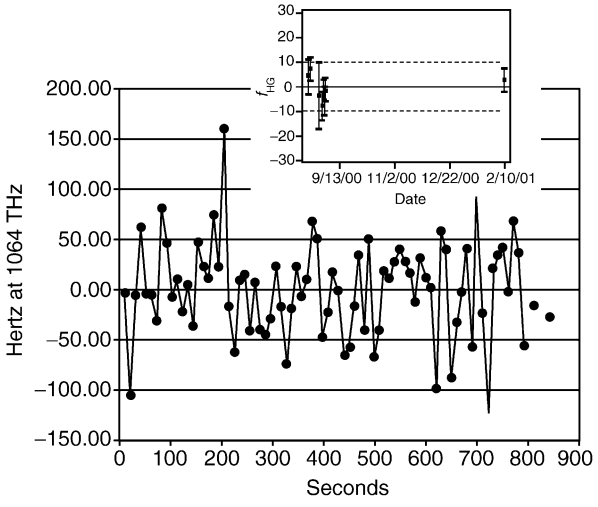

Figure 7 Actual frequency measurements of the beat-note between a hydrogen maser stabilized optical frequency comb (as shown in Figure 6) and the NIST Hg^+ optical frequency standard. The scatter in the data for counter gate time of 10 seconds corresponds to a fractional frequency uncertainty of about 4×10^{-14}, consistent within the instability in the maser. The inset shows the results from numerous datasets of measurement of the frequency of the Hg^+ optical standard relative to the cesium primary standard at NIST. The frequency data are plotted relative to 1064 721 609 899 142.6 Hz. The dotted lines give estimates of systematic uncertainties in lieu of a complete accuracy evaluation.

Table 1 Summary of optical frequency measurements of a selection of molecular, atomic, and ionic transitions. Recent measurements listed for all and additional measurements are given for a few to indicate the level of agreement

Summary of Measurements/Standards

Starting with the first measurement of the frequency of the methane-stabilized HeNe laser in 1972, a new laser frequency measurement was reported every year or so using harmonic frequency chains. These are summarized in Table 1. An indication of the history of frequency measurements of stable laser references is given in Figure 8. The accuracy, in terms of fractional frequency uncertainty, improved from 10^{-10} in 1972 to 10^{-12} in 1999, at which time the femtosecond optical frequency combs came on line and there was a dramatic improvement in the precision as well as the number of measurements that were completed. It is impossible to predict with certainty but some have projected that optical standards can ultimately reach uncertainties as small as 10^{-18}.

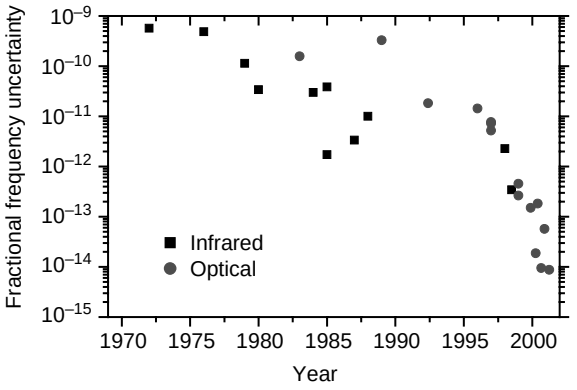

Figure 8 Progress in the accuracy of optical frequency measurements.

Outlook

Three separate technologies have now reached a level of maturity that it is possible to build high-performance optical-frequency standards and clocks. The essential achievements are: laser cooling and trapping of atoms (first proposed by Wineland and Dehmelt, and Hänsch and Schawlow), highly stabilized narrow-linewidth cw lasers, and femtosecond optical frequency combs. Combining these key ingredients, we can construct an optical atomic clock as shown schematically in Figure 9.

Here, for comparison with Figure 1, the cold atoms or single ion provide the narrow atomic resonance, the cw laser serves as the local oscillator to probe the resonance, and the femto-comb serves as the counter. Optical frequency standards of the future are expected to provide orders of magnitude better stability and improved accuracy over the existing atomic frequency standards that now use microwave transitions in atoms. As described in the previous section, frequency combs produced by femtosecond lasers can directly measure the frequency of a stable laser locked to an atomic transition relative to a known microwave frequency standard. This gives fundamental information about the atomic energy levels, and structure, and allows comparisons between different elements. However, to take

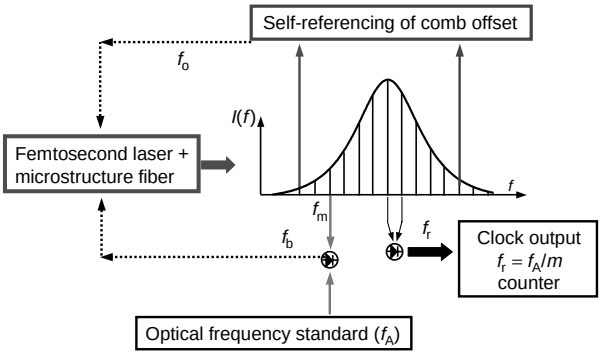

Figure 9 Simplified schematic of an optical clock.

advantage of the high stability of the optical references we run the system as an optical clock (Figure 9) where the stable laser and the femto-comb are locked to the atomic resonance, and the clock output comes as pulses at the repetition rate (e.g., 1 GHz) of the femtosecond mode-locked laser. With a judicious choice of control parameters it is possible to have the pulse repetition frequency, i.e., the clock output, at an exact subharmonic of the optical transition frequency. It is intriguing to note that a portable optical clock could measure time and length at the same time.

Fourier Transform Spectroscopy

T Fromherz, Johannes Kepler Universität, Linz, Austria

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Fourier transform spectroscopy (FTS) has emerged as one of the most powerful spectroscopic techniques since the first instruments became commercially available in the late 1960s. With this method, high spectral resolution, high wavenumber accuracy, broad spectral range, high optical throughput, and high signal to noise ratio can be achieved simultaneously. Because of these combined advantages that will be discussed in more detail throughout this article, especially in the far- (10–500 cm^{-1}) and mid-infrared (FIR and MIR) spectral region (500–5000 cm^{-1}), FTS has become the method of choice for the most sensitive spectral investigations. In this article, an overview of the setup, the working principle, and the computation of spectra from the

measured interferograms will be given. Finally, by comparing FTS to dispersive spectroscopic methods, the conditions under which FTS can be exploited to advantage, will be discussed.

Spectrometer Setup

Almost all commercially available Fourier transform (FT) spectrometers are based on a Michelson interferometer. A typical layout of this interferometer is sketched in Figure 1. A collimated beam with spectral density $S(\sigma)$ entering the spectrometer is divided into two beams by a beamsplitter. Here, σ denotes the wavenumber that is related to the wavelength (λ) of the radiation by $\sigma = 1/\lambda$. As shown in Figure 1, one part of the radiation is reflected by the beamsplitter and propagates through the compensator plate to a fixed mirror. The mirror reflects the beam through the compensator plate back onto the beamsplitter. The other part of the radiation beam is transmitted through the beamsplitter and its substrate, and hits a moveable mirror from which it is reflected back onto the beamsplitter. At the beamsplitter, both beams are divided again. As shown in Figure 1, two beams, one propagating to the source, the other propagating to the detector, finally result. Both beams contain a contribution that was reflected by the fixed mirror and a second contribution that was reflected by the moveable mirror. In Figure 1, lines indicate the paths of the beams schematically. In the case of a reflection on the beamsplitter, the line type is changed in Figure 1, whereas for a transmission, the line type remains unchanged. The widths of the lines in Figure 1 indicate the size of the field amplitudes and, therefore, are reduced for each reflection/transmission on the beamsplitter. For clarity, the lines indicating the beams reflected into themselves by the fixed and moveable mirrors in Figure 1 are offset laterally.

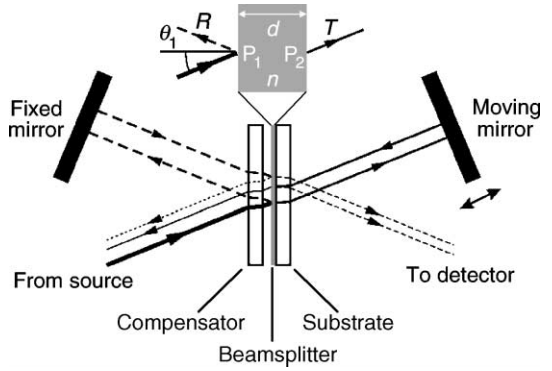

Figure 1 Schematic sketch of the layout of a Michelson interferometer. The paths of the rays are indicated by lines and arrows. At a reflection on the beamsplitter, the line type is changed, whereas for a transmission it remains unchanged. The widths of the lines indicate the size of the field amplitudes. For clarity, the lines indicating the beams reflected into themselves by the fixed and moveable mirrors, are offset laterally. The inset shows a magnified cross-section of the beamsplitter. In the inset, the geometrical details used for calculating the phase difference between R and T are defined.

By changing the position of the moveable mirror along the beam axis, a difference between the optical paths from the beamsplitter to the fixed and moveable mirror is generated. The compensator consists of the same material and has the same thickness as the beamsplitter substrate and, therefore, minimizes the influence of the dispersion of the beamsplitter substrate on the optical path difference.

Fourier Analysis and Interferometry

To calculate the intensities of the combined beams falling on the detector and on the source, we start by considering the phase difference between the reflected and transmitted beams leaving the beamsplitter. For simplicity, we ignore the compensator and beamsplitter substrate, since ideally, they generate the same phases in both arms of the interferometer, and therefore, do not contribute to the phase difference. Thus the beamsplitter is regarded as a freestanding, dielectric slab with thickness d. The complex reflection (R) and transmission (T) coefficients, including the effect of multiple internal reflections within the beamsplitter layer, are given by:

$$\begin{aligned} R &= r(1 - e^{i2\gamma})/(1 - r^2 e^{i2\gamma}) \\ T &= e^{i\gamma}(1 - r^2)/(1 - r^2 e^{i2\gamma}) \end{aligned} \quad [1]$$

Here, r is the Fresnel reflection coefficient that describes the ratio of the moduli and the phase difference between incoming and reflected electrical field for a electromagnetic wave incident under a angle Θ_1 on the surface of a dielectric with dielectric constant n, and $\gamma = 2\pi\sigma nd\cos(\Theta_2)$ is the phase difference evaluated at P_1 and P_2 in Figure 1 for a single pass of the electromagnetic wave through the dielectric slab under the angle Θ_2 (by Snellius law, $\sin(\Theta_1) = n\sin(\Theta_2)$). Since n is real, so is r and, therefore, the phase difference $\Delta\varphi$ between R and T is calculated from eqn [1] according to:

$$\begin{aligned} \frac{R}{T} &= \frac{|R|}{|T|} e^{i\Delta\varphi_{RT}} = \frac{r}{1 - r^2}(e^{-i\gamma} - e^{i\gamma}) \\ &= -2i\frac{r}{1 - r^2}\sin(\gamma) \end{aligned} \quad [2]$$

i.e., $\Delta\varphi_{RT} = -\pi/2$. With this result, we are able to calculate the phase difference between the two rays falling on the detector and the two rays falling back

on the source. The geometry considered in the following is sketched in Figure 1. The coefficients R and T connect the phases and magnitudes of reflected and transmitted electric field amplitudes at the points P_1 and P_2. From these points, the radiation beams travel back and forth to the fixed and moveable mirrors, thereby accumulating phases according to: $\varphi_f = 2\pi 2x_f\sigma$ and $\varphi_m = 2\pi 2(x_f + \Delta x)\sigma$, where we have defined $\Delta x = x_m - x_f$ and x_m, x_f denote the distances of moveable and fixed mirrors from the points P_1 and P_2. The two planewaves falling on the detector interact twice with the beamsplitter. Each planewave is once reflected at and once transmitted through the beamsplitter. Therefore, the beamsplitter adds no additional phase difference to the two planewaves and the total phase difference is given by $\Delta\varphi = \varphi_m - \varphi_f$. The situation is different for the two beams falling back on the source. Here, one beam is reflected at both interactions with the beamsplitter, whereas the other is transmitted at both interactions. According to eqn [2], between these two beams an additional phase shift of π results. Quantitatively, the total field amplitude at the detector, neglecting an arbitrary phase, is given by $E_D = E_0RT(e^{i\varphi_m} + e^{i\varphi_f})$, and the corresponding intensity is:

$$\begin{aligned} I_D \propto E_D E_D^* &= 2|E_0|^2|R|^2|T|^2\{1 + \mathrm{Re}[e^{i(\varphi_m - \varphi_f)}]\} \\ &= 2|E_0|^2|R|^2|T|^2\{1 + \cos(4\pi\sigma\Delta x)\} \end{aligned} \quad [3]$$

The sum of the field amplitudes falling back on the source is $E_S = E_0(R^2e^{i\varphi_m} + T^2e^{i\varphi_f})$. For the intensity one gets:

$$I_S \propto E_S E_S^* = |E_0|^2\{|R|^4 + |T|^4 + 2\mathrm{Re}[R^2T^{*2}e^{i(\varphi_m - \varphi_f)}]\} \quad [4]$$

Denoting the complex coefficients R and T by their modulus and their phase $R = |R|e^{i\varphi_R}$, $T = |T|e^{i\varphi_T}$ and using eqn [2], one gets:

$$I_S \propto |E_0|^2\{|R|^4 + |T|^4 + 2|R|^2|T|^2\cos(4\pi\sigma\Delta x + \pi)\} \quad [5]$$

Both intensities, I_D and I_S contain a constant component and a component that varies with $\cos(4\pi\sigma\Delta x)$. The varying parts have the same amplitude $2|E_0|^2|R|^2|T^2|$ but are out of phase by π. Consequently, a maximum in I_D corresponds to a minimum in I_S and the sum of both intensities is independent of the mirror displacement Δx.

In most of the commercially available spectrometers, only I_D is used for spectral measurements. Usually, the detector signal is amplified by an AC coupled electronics. Therefore, in a measurement of $I_D(\Delta x)$, the constant part of the signal is suppressed. Assuming a spectral density $S(\sigma)$ of the source and an ideal detector with a responsivity R_D linear in the intensity and independent of the wavenumber σ, the detector signal $D(\Delta x)$ is given by:

$$D(\Delta x) = R_D\int_0^\infty S(\sigma)\cos(4\pi\sigma\Delta x)\mathrm{d}\sigma \quad [6]$$

The information about the spectrum is contained in $S(\sigma)$ and can be extracted from the interferogram $D(\Delta x)$ by a cosine Fourier transformation. The transformation has to be done numerically and, therefore, it is more convenient to use a complex, fast Fourier transform algorithm. For that purpose, eqn [6] is modified by using the complex expansion of the cosine $\cos(x) = (e^{ix} + e^{-ix})/2$:

$$\begin{aligned} D(\Delta x) &= \frac{R_D}{2}\left(\int_0^\infty S(\sigma)e^{i4\pi\sigma\Delta x}\mathrm{d}\sigma + \int_0^\infty S(\sigma)e^{-i4\pi\sigma\Delta x}\mathrm{d}\sigma\right) \\ &= \frac{R_D}{2}\left(\int_0^\infty S(\sigma)e^{i4\pi\sigma\Delta x}\mathrm{d}\sigma + \int_{-\infty}^0 S(-\sigma)e^{i4\pi\sigma\Delta x}\mathrm{d}\sigma\right) \end{aligned} \quad [7]$$

Extending $S(\sigma)$ to negative wavenumbers according to:

$$S'(\sigma) = \begin{cases} S(\sigma) & \text{for } \sigma \geq 0 \\ S(-\sigma) & \text{for } \sigma < 0 \end{cases} \quad [8]$$

leads to the following expression for the interferogram:

$$D(\Delta x) = \frac{R_D}{2}\int_{-\infty}^\infty S'(\sigma)e^{i4\pi\sigma\Delta x}\mathrm{d}\sigma \quad [9]$$

and the spectral density $S'(s)$ can be obtained by the complex Fourier transform according to:

$$S'(\sigma) = \frac{4}{R_D}\int_{-\infty}^\infty D(\Delta x)e^{-i4\pi\sigma\Delta x}\mathrm{d}(\Delta x) \quad [10]$$

In the following, we will skip the prime and S will refer to the spectral density extended to negative values of σ.

To calculate the spectral density according to eqn [10], one has to use an interferogram extending from $-\infty$ to $+\infty$ measured at infinitely small sampling distances $\mathrm{d}(\Delta x)$. In practise, of course, the interferogram is measured only between finite mirror displacements $-\Delta x_{max}$ and Δx_{max}, at sampling points equally spaced by ξ.

The effect of the finite mirror displacement on the resulting spectral density S can be included into eqn [10] by multiplying the interferogram $D(\Delta x)$ with a function that vanishes for $|\Delta x| > \Delta x_{max}$. As an example, we use the boxcar function

$\theta(\Delta x + \Delta x_{max})\theta(\Delta x_{max} - \Delta x)$, where $\theta(x)$ is the Heaviside step function with values 0 and 1 for $x < 0$ and $x > 0$, respectively, and calculate the output spectrum for a spectral density $S_1(\sigma)$ consisting of a single line at wavenumber $\sigma_0 : S_1(\sigma) = (\delta(\sigma - \sigma_0) + \delta(\sigma + \sigma_0))/2$ (note that the spectral density is extended to negative wavenumbers according to the definitions given above). According to eqn [9], the interferogram is $D_1(\Delta x) = (R_D/2)\cos(4\pi\sigma_0\Delta x)$. Multiplying the interferogram with the boxcar function and Fourier transforming the product back using eqn [10], the resulting spectral density S_1^{box} is:

$$S_1^{box} = 2\Delta x_{max}\left\{\frac{\sin[4\pi(\sigma_0 - \sigma)\Delta x_{max}]}{4\pi(\sigma_0 - \sigma)\Delta x_{max}} + \frac{\sin[4\pi(\sigma_0 + \sigma)\Delta x_{max}]}{4\pi(\sigma_0 + \sigma)\Delta x_{max}}\right\} \quad [11]$$

Therefore, the approximation to a monochromatic spectrum is a sum of $\mathrm{sinc}(z_\pm)$ $(= \sin(z_\pm)/z_\pm)$ functions where $z_\pm = 4\pi(\sigma_0 \pm \sigma)\Delta x_{max}$. The lineshape function S_1^{box} is plotted around σ_0 in Figure 2 by the full line. Compared to the monochromatic spectrum S_1, the lines of S_1^{box} have a finite linewidth with a fullwidth at half maximum (FWHM) of approximately $0.3/\Delta x_{max}$. As a general rule in spectroscopy, two spectral lines of equal intensity and linewidth have to be separated at least by their FWHM, in order to be clearly distinguishable. According to this definition, the limit of resolution of a FT spectrometer $\Delta\sigma_{min}$ is inversely proportional to the maximum mirror displacement and given by $\Delta\sigma_{min} = 0.3/\Delta x_{max}$.

A less precise, but more intuitive definition of the resolution refers to the difference of the phases of the interferograms corresponding to two monochromatic lines separated by $\Delta\sigma$. The two lines are defined to be resolvable if the phases of their interferograms differ by more than 2π between the mirror positions $-\Delta x_{max}$ and Δx_{max}, i.e., the beating in the superposition of the interferograms shows at least one period. It is easily seen that, according to this definition $\Delta\sigma_{min} = 1/(2\Delta x_{max})$, a result in good agreement but slightly larger than that obtained by the more precise definition given above.

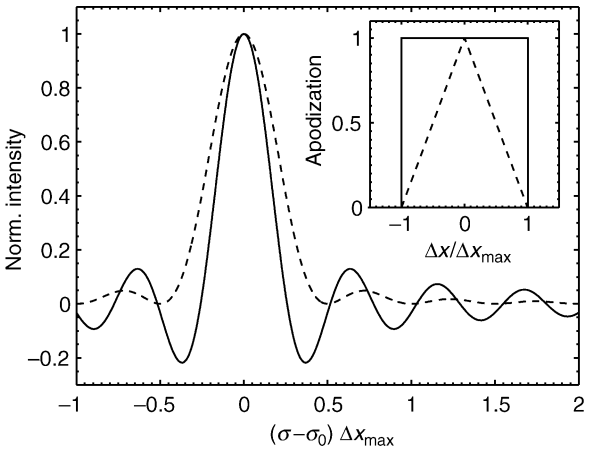

Figure 2 Normalized lineshape functions for boxcar (full line) and triangular apodization (broken line). In the inset, the corresponding apodization functions are shown.

As shown in Figure 2 by the full line, the sinc function has negative side-lobes with magnitudes of up to 22% of the maximum value. For some spectroscopic applications this side lobes are unwanted since they lead to a suppression of smaller peaks separated by approximately the resolution limit of the spectrometer. Thus, in these cases, it appears to be reasonable to multiply the interferogram by a (apodization) function different from the natural boxcar function. Usually, triangular or trapezoidal functions vanishing for $|\Delta x| > \Delta x_{max}$ are used. By Fourier transformation of these functions, it can be shown that no negative side lobes are generated. However, these functions have a larger (up to ~50%) peak FWHM than the sinc function. For comparison, in Figure 2, also the lineshape of a monochromatic spectrum using a triangular apodization function $A(\Delta x) = \theta(\Delta x + \Delta x_{max})\theta(\Delta x_{max} - \Delta x)(1 - |\Delta x/\Delta x_{max}|)$ is shown by the broken line. In this case, the negative sidelobes are strongly suppressed but the FWHM is increased.

Generally, the output spectrum $S^A(\sigma)$ corresponding to an arbitrary spectral density $S(\sigma)$ and an apodization function $A(\Delta x)$ is given by the convolution $S^A(\sigma) = 2[S \otimes A^{FT}](\sigma)$, where the lineshape function A^{FT} is the Fourier transform of $A(\Delta x)$:

$$A^{FT}(\sigma) = \int_{-\infty}^{\infty} A(\Delta x)e^{-4\pi\sigma\Delta x}d(\Delta x) \quad [12]$$

and

$$[f \otimes g](t) \equiv \int_{-\infty}^{\infty} f(\tau)g(t - \tau)d\tau \quad [13]$$

Discrete Sampling

In order to discuss the effect of the discrete, equally spaced sampling points with a mutual distance of ξ on the output spectrum, Δx is replaced by $x_n = n\xi$ in eqn [10], where n is an integer and runs from $-N_{max}$ to N_{max} and $N_{max}\xi = \Delta x_{max}$. Instead of the continuous interferogram $D(\Delta x)$, a discrete interferogram:

$$D_n = \frac{R_D}{2}\int_{-\infty}^{\infty} S(\sigma)e^{i4\pi n\xi\sigma}d\sigma \quad [14]$$

results. From eqn [14], it is readily seen (by shifting the integration variable) that replacing $S(\sigma)$ with $S[\sigma + m/(2\xi)]$, where m is an integer, does not change the discrete interferogram D_n. Keeping in mind that according to our definition $S(-\sigma) = S(\sigma)$, it is clear that $S[-\sigma + m/(2\xi)]$ also leads to the same interferogram as $S(\sigma)$. Therefore, to be able to transform the interferogram to the spectral density $S(\sigma)$ for a wavenumber band $[0, \sigma_{max}]$ unambiguously, one has to make sure, by electronically and/or optical filtering, that no wavenumbers outside this range contribute to the interferogram and that the sampling interval ξ is small enough so that $\sigma_{max} < -\sigma_{max} + 1/(2\xi)$, i.e., $\sigma_{max} < 1/(4\xi)$. In Figure 3, a schematic sketch of a spectral density $S(\sigma)$, consisting of two spectral bands shown by the full and dashed lines, is plotted. For the spectral band shown by the full line, the sampling interval ξ is small enough so that in the interval $[0, 1/(4\xi)]$ no ambiguity arises. For the spectral band shown by the dashed line, the interferogram appears to be under-sampled: ξ is too large, and, therefore, the part of the spectral band at negative wavenumbers shifted by $+1/(2\xi)$ falls into the interval $[0, 1/(4\xi)]$ (shown by the dotted line in Figure 3). Thus, for the sampling interval ξ, the interferogram for the sum of spectral bands, shown by the full and the dashed lines in Figure 3, is the same as for the sum of the spectral bands shown by the full and dotted lines. Since the interferograms are the same, the two spectra are indistinguishable at sampling intervals ξ. This ambiguity of spectra for an under-sampled interferogram is called aliasing. Comparing the correct sampling interval $\xi < 1/(4\sigma_{max})$ with the period of the interferogram D_n corresponding to a spectrum consisting of a single line at σ_{max} ($D_n = R_D \cos(4\pi n\xi\sigma_{max})$), it follows that the interferogram has to be sampled more than two times per period in order to obtain an unambiguous result (Nyquist Theorem).

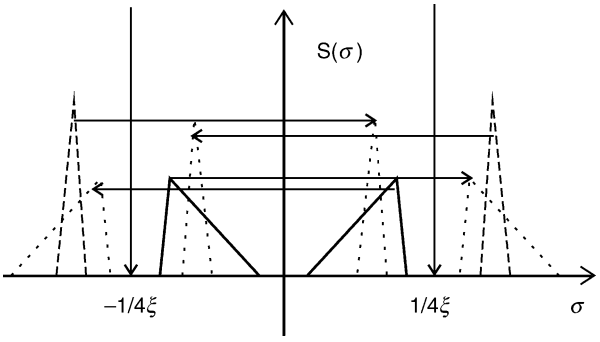

Figure 3 Schematic sketch of aliasing for under-sampled interferograms. For spectral density shown by the full line, the sampling interval ξ is chosen correctly and the $1/(2\xi)$ wavenumber ambiguity indicated by the arrows in the plot does not result in erroneous features in the spectral range $[0, 1/(4\xi)]$. The situation is different for the spectral band sketched by the dashed line: For this band, the sampling interval ξ is too large, and consequently, the $1/(2\xi)$ wavenumber ambiguity maps the line from the negative wavenumber region into the range $[0, 1/(4\xi)]$. The mapped spectral band is indicated by the dotted line.

Mathematically, the spectral density is calculated from the discrete interferogram D_n by a discrete Fourier transformation:

$$S_m = \frac{2}{R_D N} \sum_n^N D_n e^{-2\pi i n m/N} \qquad [15]$$

where N is the number of sampling points ($N = 2N_{max} + 1$) and the wavenumbers corresponding to S_m are given by $\sigma_m = m/2\xi N$.

In order to obtain a high accuracy in the sampling intervals ξ, usually a reference interferogram of a monochromatic laser line (for example from a HeNe laser) is measured simultaneously with the interferogram of the actual experiment. By counting, for example, the zeros with positive slope in the interferogram of the laser line, uniformly spaced sampling points can be achieved with high accuracy. If, in an experiment many interferograms have to be averaged, the absolute position of the sampling points is important, in order to ensure that only points of equal mirror displacement are averaged. Therefore, in some spectrometers, the interferogram of a broadband source is measured simultaneously with the interferograms of the laser and the experiment and the maximum of the interferogram of the broadband source is taken as the origin for counting the zeros of the laser interferogram.

Phase Correction

Ideally, the interferogram is expected to be symmetrically around the position of equal optical path in the two arms of the interferometer. However, in practise this is seldom the case. Many reasons can lead to an asymmetric interferogram, the most obvious being that none of the discrete sampling points of the interferogram coincides with the mirror position for equal optical path in the two interferometer arms. Let Δx_m be the measured mirror displacement that differs from the real mirror displacement Δx by x_0, i.e., $\Delta x = \Delta x_m + x_0$. In that case the measured interferogram is:

$$D(\Delta x_m) = \frac{R_D}{2} \int_{-\infty}^{\infty} S(\sigma) e^{i[4\pi\sigma(\Delta x_m + x_0)]} d\sigma \qquad [16]$$

and the Fourier transformation, according to eqn [10] with Δx_m as the integration variable, results in

$S(\sigma)e^{i4\pi x_0\sigma}$, that is, in a spectrum with both real and imaginary parts. Also, mirror or compensator misalignment can result in a wavenumber-dependent optical path at a fixed mirror position. Finally, for rapid-scan interferometers, in that the movable mirror is scanned at a constant velocity v, the electronic filtering and amplification of the detector signal will also add different phases, depending on the signal frequency ν that is correlated to the wavenumber σ by $\nu = 2\sigma v$. In general, as long as the phase φ depends only on the wavenumber and not on the mirror displacement, the measured interferogram is:

$$D(\Delta x_m) = \frac{R_D}{2}\int_{-\infty}^{\infty} S(\sigma)e^{i[4\pi\sigma\Delta x_m+\varphi(\sigma)]}d\sigma \qquad [17]$$

and by the Fourier transformation, according to eqn [10], one obtains $S(\sigma)e^{i\varphi(\sigma)}$. There are several methods implemented in the software of commercially available Fourier spectrometers to eliminate the phase from the Fourier transform. In most experimental cases, in that the measured interferograms correspond to spectra with $S(\sigma) \geq 0$ for all $\sigma \in [0, \sigma_{max}]$, these methods usually give the correct results. However, care has to be taken if spectra contain positive and negative components. This can be the case, for example, if the transmission of a sample is periodically modulated by externally applied voltage or a laser light and the detector signal is amplified by a lock-in technique before it is fed into the electronics of the Fourier transform spectrometer. If the modulation increases the sample absorbance in one part of the spectral range and decreases it in a different part, then the measured interferogram corresponds to a spectrum with both negative and positive regions. In the following, first the phase correction methods for spectra with positive values only are discussed before it is argued, why these methods might fail for spectra with positive and negative parts.

For spectra with only positive values, the most simple method to eliminate the unknown phase is to measure the interferogram symmetrically around $\Delta x_m = 0$ and calculate $S(\sigma)e^{i\varphi(\sigma)}$ according to eqn [10]. Including the effect of finite scan length, the output spectrum becomes $S^A = 2[S(\sigma)e^{i\varphi(\sigma)}]\otimes A(\sigma)^{FT}$. Under normal experimental conditions, the phase $\varphi(\sigma)$ does not vary over the peak FWHM of $A(\sigma)^{FT}$ and, therefore, the phase term can be put outside the integral of the convolution and $S^A = 2e^{i\varphi(\sigma)}[S(\sigma)\otimes A(\sigma)^{FT}]$ results. Since $A(\Delta x_m) \geq 0$, and chosen to be symmetric around $\Delta x_m = 0$, the convolution is real and positive and the true spectrum with instrumental resolution $2[S(\sigma)\otimes A(\sigma)^{FT}]$ can be obtained by calculating the modulus of S^A without any knowledge about $\varphi(\sigma)$. However, for several reasons this method for phase correction is not ideal. First of all, since the maximum spectral resolution of a Fourier transform spectrometer is inversely proportional to the maximum mirror displacement, for a given spectrometer layout with a fixed maximal mirror scan length L, the maximal achievable spectral resolution is reduced by a factor of two if scans symmetric around $\Delta x = 0$ have to be performed. Secondly, for signals closer to or smaller than the noise level of the spectrometer, the random noise will be entirely positive by taking the modulus. Hence, for small signals, the noise level will be increased relative to the signal level by taking the modulus.

Therefore, usually the 'Mertz phase correction method' is used. This method is based on the assumption that the phase $\varphi(\sigma)$ is a slowly varying function of σ. In this case, $\varphi(\sigma)$ can be determined with low spectral resolution, i.e., by a short, symmetric scan of length $2L_1$ around $\Delta x = 0$. It can be shown that from this scan the phase can be obtained according to:

$$\varphi(\sigma) = \arctan\left\{\frac{\mathrm{Im}[S(\sigma)e^{i\varphi(\sigma)}\otimes A^{FT}(\sigma)]}{\mathrm{Re}[S(\sigma)e^{i\varphi(\sigma)}\otimes A^{FT}(\sigma)]}\right\} + \pi \text{ (if denominator is negative)} \qquad [18]$$

Here, $S(\sigma)e^{i\varphi(\sigma)}\otimes A(\sigma)^{FT}$ results from the Fourier transformation of the short interferogram measured between $-L_1$ and L_1 and the apodization function $A(\Delta x_m)$ is adjusted to $-L_1$ and L_1. The addition of π for negative denominators is a consequence of the assumption that $S(\sigma)$ is positive everywhere. Under this assumption, a negative denominator in eqn [18] corresponds to a phase angle $|\varphi(\sigma)| > \pi/2$, that is mapped into $[-\pi/2, \pi/2]$ by the arctan-function. To get the correct phase angle, π has to be added to the phase angle, thereby extending the range of $\varphi(\sigma)$ to $[0, 2\pi]$.

With $\varphi(\sigma)$ known, the interferogram has to be recorded only for mirror displacements $\Delta x_m \geq 0$, since the information about the interferogram for $\Delta x_m < 0$ is contained in the phase spectrum and the interferogram for $\Delta x_m \geq 0$. Therefore, with this method, the totally available mirror displacement length can be used for increasing the spectral resolution.

However, for spectra containing positive and negative spectral bands, the Mertz phase correction usually fails, due to the addition of π if the denominator in eqn [18] becomes negative. For spectra with positive and negative bands, the sign of the denominator is determined by both $S(\sigma)$ and $\varphi(\sigma)$. Applying the Mertz algorithm in a negative region of

the spectrum with a vanishing physical phase angle, results in a calculated phase angle of $\varphi = \pi$. As a consequence, the negative spectral band appears as a positive band in the output spectrum calculated according to the Mertz algorithm.

To avoid erroneous phase-flips, the addition of π in eqn [18] for negative denominators can be omitted and the allowed values for $\varphi(\sigma)$ are reduced to $[-\pi/2, \pi/2]$. The corresponding phase correction method is usually referred to as the 'Mertz signed method'. However, it is immediately clear from the discussion above, that in this case any physical phase angle outside the range $[-\pi/2, \pi/2]$ results to an erroneous π-jump of the phase. According to eqn [16], a physical phase shift larger than $\pi/2$ can, for example, be the consequence of a large offset x_0, i.e., of an inaccurate alignment of Δx_m and Δx. At $\Delta x = 0$, all contributions to the interferogram add constructively and the height of the interferogram is proportional to the area under the spectral curve $S(\sigma)$, as can be readily seen by setting $\Delta x = 0$ in eqn [10]. Therefore, for $S(\sigma) > 0$ the position $\Delta x_m = 0$ is usually estimated by the global maximum of the measured interferogram. However, for spectra with both positive and negative bands, in most cases the interferogram does not exhibit a maximum at $\Delta x = 0$ (for positive and negative bands of equal height and width, the interferogram vanishes at $\Delta x = 0$), and estimating $\Delta x_m = 0$ by an extremum of the interferogram results, therefore, in a large offset x_0. Thus, in order to be able to use the 'Mertz signed' algorithm, $\Delta x_m = 0$ has to be determined separately in a calibration experiment in that the condition $S(\sigma) > 0$ is fulfilled. However, even for accurately determined $\Delta x_m = 0$, erroneous phase jumps can appear if lines of different intensity and opposite sign are spaced approximately equal to the resolution used for determining the phase spectrum $\varphi(\sigma)$.

In conclusion, there are no general strategies to completely exclude phase jumps in the Fourier transformation of interferograms corresponding to spectra with positive and negative bands. The experimentalist has to check from case to case if lines with strange shapes appear in the output spectra, and modify the phase correction accordingly. More elaborate strategies for phase correction, that are beyond the scope of this article, are reported in literature.

Example of Experimental Results

To illustrate the features of FTS discussed in the previous paragraphs by a practical example, in Figure 4 the results of a typical measurement in the MIR between 500 cm^{-1} and 5000 cm^{-1} are shown. The experiments were performed with a BRUKER IFS113 spectrometer using a silicon carbide glowbar as a source for the infrared radiation, a potassium bromide beamsplitter, and a liquid-nitrogen cooled mercury cadmium telluride detector. The spectrometer used for the experiments is set up in a vacuum chamber. The two interferograms shown in Figure 4a were measured at two different pressures (broken line: 10 mbar; full line: 300 mbar), i.e., at two different levels of absorption of the atmospheric gas in the interferometer chamber (for clarity, the interferograms are offset vertically). The abscissa axis is broken in Figure 4a and shows portions of the interferograms around zero mirror displacement and around the maximum mirror displacement of 2.5 cm (chosen for 0.2 cm^{-1} spectral resolution). For higher chamber pressures, the increased absorption of the atmospheric gas results in an increased amplitude of the wiggles of the interferogram apparent for large mirror displacements in Figure 4a. The amplitude of these wiggles is approximately three orders of magnitude smaller than the detector signal observed at the center-burst of the interferogram around zero mirror displacement. However, in the corresponding spectra (Figure 4b) calculated from the interferograms after phase correction, the absorption of the atmospheric gas is clearly evident by a strong increase of the dense and narrow absorption lines in the spectral regions 1200 cm^{-1}–2200 cm^{-1}, 2300 cm^{-1}–2400 cm^{-1}, and 3200 cm^{-1}–4000 cm^{-1} (note that in Figure 4b the spectra are offset vertically by 0.1 for clarity). The lines observed between 2300 cm^{-1}–2400 cm^{-1} are due to absorption of the CO_2 molecule and are shown in more detail in Figure 4c from 2335 cm^{-1} to 2345 cm^{-1}. In order to simulate the contribution of the CO_2 lines to the interferogram shown in Figure 4a, two neighboring lines in Figure 4c were fitted to a doublet of Lorentz-absorption lines (indicated by the symbols in Figure 4c). The corresponding interferogram was calculated by Fourier transformation of the Lorentz lines and is shown in Figure 4d. It consists of a rapid oscillating, cosine-like signal (see inset for an expanded plot between 0.6 and 0.602 cm) with an amplitude modulation corresponding to the difference of the resonance wavenumbers of the two Lorentz lines. The ordinate axes of Figures 4a,d have the same arbitrary units and, therefore, the amplitudes of the interferograms shown in these two panels can be directly compared. From Figure 4a, d we conclude that the two CO_2 lines contribute approximately with only one in 10^5 parts to the center-burst of the measured interferogram, i.e., theses lines absorb only a fraction of 10^{-5} of the integrated (over the wavenumbers) intensity of

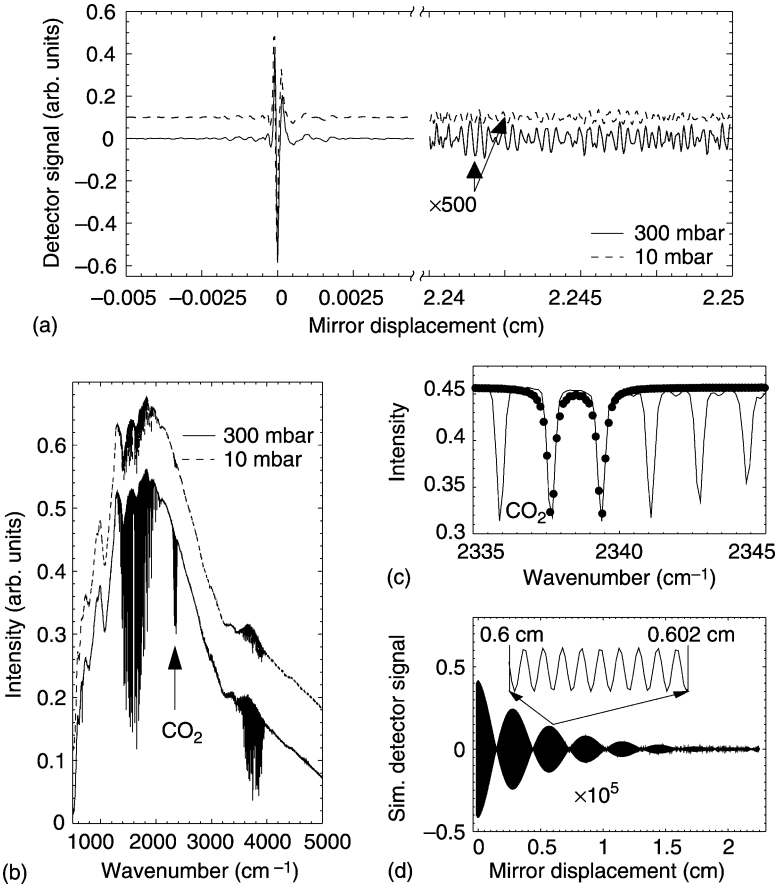

Figure 4 Measurement of the absorption of atmospheric gas for different pressures in the interferometer chamber (broken lines: 10 mbar, full lines: 300 mbar). (a) Interferograms (note the break in the axis of the mirror displacement). For clarity, the interferograms are offset vertically by 0.1 and 0.0002 on the left and right side of the axis break. On the right side of the axis break, the interferograms are amplified by a factor 500. (b) Spectra corresponding to the interferograms shown in (a). The spectra are offset vertically by 0.1 for clarity. (c) Part of the CO_2 absorption lines on an expanded wavenumber axis. The symbols indicate a fit of two Lorentz lines to neighbouring CO_2 absorption lines. The fit is used for calculating the interferogram shown in (d). (d) Simulated interferogram corresponding to the two CO_2 lines shown by the symbols in (c). The arbitrary units of the ordinate axis are the same as those used in (a) but the interferogram is amplified by a factor 10^5. In the inset, the interferogram is shown on an enlarged scale between 0.6 and 0.602 cm mirror displacement.

the incident radiation. Despite this small fraction, they are extremely well resolved with a large signal-to-noise ratio in Figures 4b,c, thus demonstrating the ability of FTS to measure spectra simultaneously with high resolution and over a large spectral range. This ability is one of the advantages (the so-called multiplex advantage) inherent in FTS and will be discussed in more detail in the following paragraph.

Advantage of FTS Over Dispersive Spectrometer

The two main advantages of FTS over dispersive spectroscopic methods, using, for example, a grating for the spectral decomposition of an incoming radiation, are directly connected with the working principle of FT spectrometers; high optical throughput and multiplexed measurement over the whole spectral range of interest. These advantages are discussed in the following, in more detail.

For a fair comparison of the optical throughput, spectrometers with equal spectral resolving power ρ have to be compared. Here, $\rho = \sigma_{max}/\Delta\sigma$, where σ_{max} is the maximum wavenumber analyzed and $\Delta\sigma$ is the spectral resolution. For an ideal Fourier transform spectrometer, the limit for σ_{max} depends on the divergence angle of the beams propagating in the spectrometer. As sketched in Figure 5, the divergence angle α is determined by the radius r_a of the entrance aperture and the focal length f of the collimating lens by $\alpha \approx r_a/f$. This angle causes a phase shift between the rays propagating parallel to and those propagating under the angle of α inclined to the optical axis

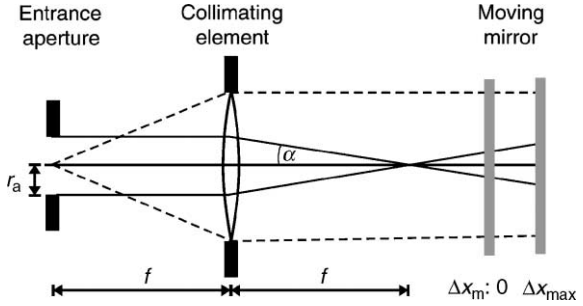

Figure 5 Entrance aperture and collimating element for an interferometer. For simplicity, the beamsplitter and fixed mirror are omitted in the sketch. The extreme rays entering the interferometer are indicated by the full and broken lines. Due to divergence α, a monochromatic light with wavenumber σ_0 produces all periods in the range $[4\pi\sigma_0, 4\pi\sigma_0/\cos(\alpha)]$ in the interferogram.

through the interferometer. The phase difference φ_{div} depends on the mirror displacement according to $\varphi_{div} = 4\pi\sigma\Delta x((1/\cos(\alpha)) - 1)$ and can be approximated for small α by $\varphi_{div} \approx 2\pi\sigma\Delta x\alpha^2$. It can be shown, that as long as φ_{div} does not exceed approximately π, the influence of the divergence on the interferogram can be tolerated, i.e., $\sigma_{max} \approx 1/(2\Delta x_{max}\alpha^2)$. Using $\Delta\sigma \approx 1/(2\Delta x_{max})$ for the resolution, one obtains for the resolving power of a FT spectrometer, $\rho = (f/r_a)^2$.

The optical throughput Θ describes the allowable energy per unit time that the system can let through and is related to area πr_a^2 of the aperture and the solid angle Ω of the collimating (or focusing) optics by $\Theta = \pi r_a^2\Omega$. Using $\Omega = A_{FTS}/f^2$, where A_{FTS} is the clear area of the collimating lens (for a collimating mirror, A_{FTS} is the area of the mirror projected on a plane perpendicular to the beam direction), results in $\Theta_{FTS} = \pi A_{FTS}r_a^2/f^2 = \pi A_{FTS}/\rho$. For a grating spectrometer, $\Theta_{grating} = hA_G/f\rho$. (see respective chapter of this encyclopedia) where h is the height of the slit, f the focal length of the collimating optics, and A_G the projected area of the grating. Generally, h/f is smaller than 1/20 in up-to-date grating spectrometers. Thus, for the same resolving power ρ and similar instrument size, FT spectrometer can offer a more than $\pi f/h \approx$ 60 times larger energy gathering capability. Therefore, for measurements with weak signals in that the detector noise is the dominant noise source, the large throughput of a FTS greatly increases the spectral signal to noise ratio that can be achieved for a fixed measuring time.

The other major principal advantage compared to dispersive methods relies on the simultaneous (multiplexed) gathering of information about all spectral bands $\Delta\sigma$ over a broad spectral range from σ_{min} and σ_{max}. For a grating spectrometer using a single detector element, the measurement time T_m available for recording the spectrum in that range has to be distributed between the $M = (\sigma_{max} - \sigma_{min})/\Delta\sigma$ spectral bands so that for a single spectral band the available integration time is T_m/M and the integrated signal increases proportional to T_m/M. If the dominant noise source is the detector noise which is independent of the signal level, then the noise will be proportional to $(T_m/M)^{1/2}$ and, therefore, the signal to noise ratio for the grating spectrometer $(S/N)_G$ is:

$$(S/N)_G \propto (T_m/M)^{1/2} \qquad [19]$$

For a FTS the situation is different, since it detects in the band $[\sigma_{min}, \sigma_{max}]$ all M small bands over the whole measurement time T_m via their contribution to the interferogram. So the integrated signal in a small band $\Delta\sigma$ is proportional to T_m. If the noise is again assumed to be random and independent of the signal level, for the FTS:

$$(S/N)_{FTS} \propto T_m^{1/2} \qquad [20]$$

results. For the same detector, assumed in the grating spectrometer and in the FTS, the proportionality constants are the same in eqns [19] and [20] and, therefore

$$\frac{(S/N)_{FTS}}{(S/N)_G} = M^{1/2} \qquad [21]$$

Equation [21] shows that the multiplex advantage becomes increasingly important for measurements of broad spectral bands with high resolution. In this case, an enhancement of the $(S/N)_{FTS}$ over $(S/N)_G$ by 2–3 orders of magnitude can be achieved. However, it has to be noted that the multiplex advantage of a FTS can be exploited only in cases where the detector noise is the dominant source of noise. In the visible and near infrared spectral region, low noise detectors, that allow single photon detection, are available. With these detectors, the spectral noise is dominated by the photon noise that is proportional to the square root of the intensity. It is evident that in this case the multiplexed detection is not an advantage, since for M spectral bands of width $\Delta\sigma$ contributing to the interferogram at a given mirror position, the noise is enhanced by $M^{1/2}$ compared to the noise that would be measured for a single band (here, it is assumed that all M bands contribute with the same intensity to the interferogram). Consequently, in this case, the noise enhancement by $M^{1/2}$ cancels the beneficial factor $M^{1/2}$ in eqn [21] and with single-detector grating and FT spectrometers, the same S/N ratio is achieved for a given measurement time T_m. In addition, using linear detector arrays with dispersive spectrometers, the multiplex advantage increases the S/N ratio for the dispersive spectrometer. However, detector arrays

and low-noise detectors are mainly available for spectral regions with $\sigma > 6000\ \mathrm{cm}^{-1}$, i.e., in the near-infrared and visible spectral region. In the FIR and MIR region ($\sigma < 6000\ \mathrm{cm}^{-1}$) in that such detectors are absent, the multiplexing inherent in FTS makes it the method of choice if low-noise, broadband, and high-resolution spectroscopic data are required.

List of Units and Nomenclature

Angle of incidence for radiation on beamsplitter	Θ_1
Angle of propagation of radiation in the beamsplitter layer	Θ_2
Beam divergence angle	α
Beam splitter thickness (cm)	d
Complex reflection coefficient	R, r
Complex transmission coefficient	T, t
Detector Signal normalized to detector area ($\mathrm{A\ cm}^{-2}$)	D
Difference between real and measured mirror displacement (cm)	x_0
Dirac delta-function	δ
Discrete interferogram ($\mathrm{A\ cm}^{-2}$)	D_n
Discrete spectral density ($\mathrm{W\ cm}^{-1}$)	S_m
Distance from beamsplitter to fixed mirror (cm)	x_f
Distance from beamsplitter to movable mirror (cm)	x_m
Electric field amplitude of incident radiation (V/m)	E_0
Electric field amplitude of radiation falling back on source (V/m)	E_S
Electric field amplitude of radiation reaching detector (V/m)	E_D
Focal length (cm)	f
Fourier transform of apodization function A (cm)	A^FT
General apodization function	A
Heavyside step function	θ
Intensity falling back on source ($\mathrm{W\ cm}^{-2}$)	I_S
Intensity on detector ($\mathrm{W\ cm}^{-2}$)	I_D
Maximum mirror displacement (cm)	Δx_max
Maximum wavenumber (cm^{-1})	σ_max
Measured mirror displacement (cm)	Δx_m
Measured single line spectral density for a finite scan length ($\mathrm{W\ cm}^{-1}$)	S_1^box
Measured single line spectral density for a finite scan length using the apodization function A ($\mathrm{W\ cm}^{-1}$)	S^A
Measurement time for complete spectrum (s)	T_m
Minimum wavenumber (cm^{-1})	σ_min
Mirror displacement	Δx
Mirror velocity ($\mathrm{cm\ s}^{-1}$)	v
Modulation frequency (s^{-1})	ν
Number of sampling points of the interferogram	N
Number of spectral bands	M
Optical throughput (cm^2)	Θ
Optical throughput for FTS (cm^2)	Θ_FTS
Optical throughput for grating spectrometer (cm^2)	Θ_grating
Phase accumulation due to optical path to fixed mirror	φ_f
Phase accumulation due to optical path to moveable mirror	φ_m
Phase angle	γ
Phase angle	φ
Phase difference	$\Delta\varphi$
Phase difference between beams reflected at and transmitted through beamsplitter	$\Delta\varphi_\mathrm{RT}$
Phase difference due to beam divergence	φ_div
Phase jump for reflection at beamsplitter	φ_R
Phase jump for transmission through beamsplitter	φ_T
Projected area of collimating element of FTS (cm^2)	A_FTS
Projected area of grating (cm^2)	A_G
Radius of entrance aperture (cm)	r_a
Refractive index	n
Responsivity ($\mathrm{A\ W}^{-1}$)	R_D
Sampling interval (cm)	ξ
Signal to noise ratio for FTS	$(\mathrm{S/N})_\mathrm{FTS}$
Signal to noise ratio for grating spectrometer	$(\mathrm{S/N})_\mathrm{G}$
Single line spectral density ($\mathrm{W\ cm}^{-1}$)	S_1
Solid angle	Ω
Spectral bandwidth (cm^{-1})	$\Delta\sigma$
Spectral density ($\mathrm{W\ cm}^{-1}$)	S
Spectral resolving power	ρ
Wave length (μm)	λ
Wave number (cm^{-1})	σ, σ_0
Wave number resolution (cm^{-1})	$\Delta\sigma_\mathrm{min}$

Introduction

Consider the task of measuring the spectra of a source, the spectra of an array of contiguous sources, or simply the broadband irradiance of an array of sources. These measures are commonly known as spectrometry, spectral imaging, and imaging, respectively. The sensitivity at which spectrometric, spectral imaging, and imaging systems can be operated is often dominated by noise associated with the detection system and the ability of the optics employed to deliver sufficient photonic flux to the detector subsystem to overcome this noise limitation. The ideal case is where the optical system can be fashioned in such a way as to deliver greater signal to the detector in order to maximize the signal-to-noise ratio (SNR) for a given finite source irradiance and detector noise.

Let us consider the number of discrete spectral resolution elements of spectrometers, spatio-spectral resolution elements of spectral imagers, and spatial resolution elements of imaging systems as being the N quantities of interest we would like to measure. We wish to measure these N quantities in time T with the greatest accuracy and precision as determined by the maximum SNR possible given a finite source flux and a fixed detector noise floor. One option might be to use a multi-element detection system (multi-channel detection system) with N detectors, so each detector is measuring one of the N quantities for the full time T in order to maximize the available integration time. However, in practice, these detectors can be problematic or simply not available for many applications when compared to single-element detectors. When a single-element detector is employed in spectrometry, spectral imaging, or imaging, the measurement methodology required becomes N measurements, each for a time T/N, so that each of the N quantities is measured separately or alternatively, one can record N measurements, each for time T/N, for various groups of the N quantities. The measurement procedure for various groups of the N quantities requires an encoding procedure to choose which of the N quantities to include in each of the N measurements and a decoding procedure to recover the values for each of the N individual quantities. When combinations of N quantities are measured, the signal at the single detector element is increased and the procedure is called multiplexing. Multiplexing may be defined as measuring the sum of groups of quantities rather than measuring each quantity separately with the primary goal of increasing SNR. Multiplexing can and does increase SNR when the detection system of the measuring device is operating in the detector noise limit. The detector noise limit is defined as the noise of the detector output that is independent of the amplitude of the signal. Photon-noise-limited detector systems can benefit from multiplexing strategies, however, one must be careful not to realize a multiplex disadvantage when the source of noise is not detector noise limited.

Fourier Transform Multiplexing

In optical spectrometry a common multiplexing method employs the Michelson interferometer in a Fourier transform (FT) spectrometer where, in the best case, as much as half of the spectral energy of the source entering the aperture is incident upon the single detector element for the duration of the measurement. The output of the detector is recorded as an interferogram, which is the detector response as a function of optical retardation (twice the path difference between the arms of the Michelson interferometer). The recorded interferogram is decoded using a Fourier transform algorithm to yield the desired spectrum. FT spectrometers are routinely employed in near-infrared, mid-infrared, and

far-infrared spectrometry. In Raman spectrometry, FT spectrometers are used in the near-infrared spectral region typically using an Nd:YAG laser providing an excitation wavelength of 1064 nm. FT techniques are also employed in nuclear magnetic resonance (NMR) spectrometry and mass spectrometry.

Hadamard Transform Multiplexing

Hadamard transform multiplexing in dispersive optical spectrometry can be accomplished by use of an encoding mask at the focal plane of a dispersive spectrometer, that is operable to select different combinations of spectral resolution elements that are allowed to pass to the single detector element for each of the N required measurements. The specification of which ones of the N quantities are included in each of the N measurements of groups of the N quantities is called a weighing design. The term weighing design originally referred to a procedure for accurately determining the mass of a number of objects by weighing them in groups rather than one at a time. The optimal weighing designs and corresponding optimal encoding masks are specified by Hadamard mathematics. The Hadamard matrix or $\mathbf{H}$ matrix has all elements of $+1$ and -1 and provides the optimal weighing design for a two-pan balance or an optical instrument having two detector elements for the $+1$ and -1 measures. The Hadamard matrices specify which quantities go to each balance pan or detector element.

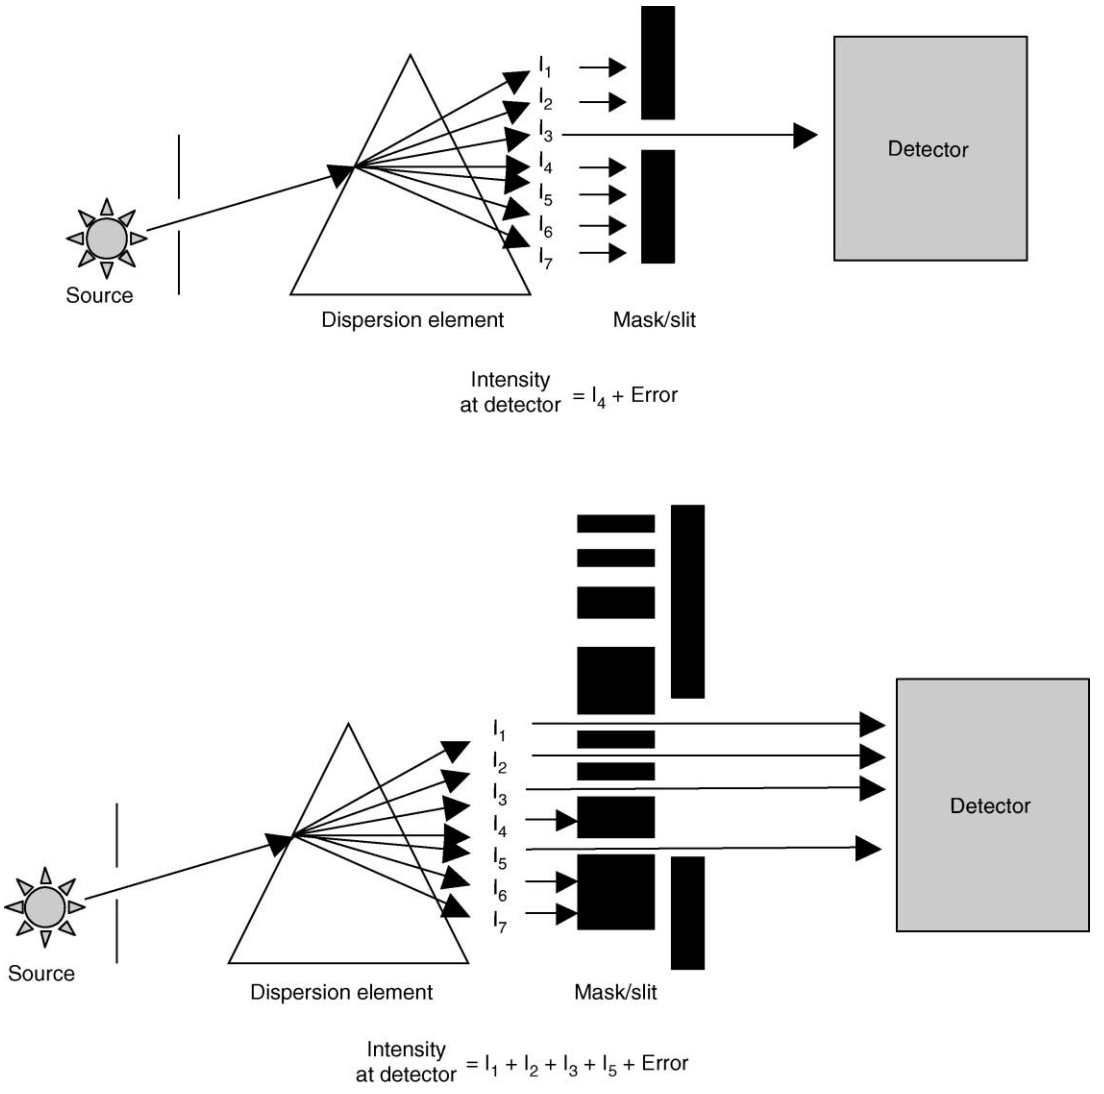

Figure 1 Simple schematic of a conventional and a Hadamard transform spectrometer. The top shows a conventional spectrometer where only one of seven spectral resolution elements ($N = 7$) impinge upon the single element detector for each of N measurements. The bottom shows a Hadamard transform spectrometer where $N = 7$. One more than half of the spectral resolution elements impinge upon the single element detector for each of the N measurements.

One and Two Detector Hadamard Encodement Matrices

In the case of a dispersive spectrometer with a single detector element, the optimal weighing designs and corresponding optimal encoding masks are provided by the simplex matrix or **S** matrix derived from the **H** matrix. The type of **S** matrix that is most convenient for optical applications is the cyclic or left circulant **S** matrix where only the first row needs to be known to generate the complete cyclic **S** matrix of N columns and N rows. Each row is obtained by shifting the previous row by a left-shift registration in which the element in the far left column moves to the far right column of the next row and each of the other $N-1$ elements moves one column to the left. Each of the N rows of the cyclic **S** matrix specifies one of the N encodements and each of the N columns specifies one of the N spectral resolution elements. The elements of the cyclic **S** matrix are 1 and 0 instead of the $+1$ and -1 found in the **H** matrix implementation. Spectral resolution elements allowed and not allowed to reach the single detector element are given as 1's and 0's, respectively. Each row and each column of the cyclic **S** matrix is a different sequence of $(N+1)/2$ elements of 1's and $(N-1)/2$ elements 0's so that each encodement in the row of the cyclic **S** matrix has a different combination of $(N+1)/2$ spectral resolution elements that are incident upon the single detector element. Just as the positions of the 1's in a row show which spectral resolution elements are included in a particular encodement, the positions of the 1's in a column show which encodements include that particular spectral resolution element. The result is that provided the detector noise is independent of its output signal, the SNR is increased by a factor of $(N+1)/(2\sqrt{N})$, approximately $(\sqrt{N})/2$, when compared to the method of measuring each spectral resolution element separately as in a raster scan performed by a classical scanning dispersive spectrometer.

Multiplexing in dispersive optical spectrometry as introduced in the previous paragraph is called Hadamard transform spectrometry (HTS) (see Figure 1). It is a unique combination of dispersive and multiplexing spectrometries. The choice of transparent or opaque for the elements of a multislit array or Hadamard encoding mask provides an encoding of spectral information that may be decoded into a conventional spectrum by Hadamard mathematics. In a typical dispersive spectrometer, the source energy is collected and separated into its individual spectral resolution elements by a spectral separator and then collected and focused for spatial presentation on a focal plane. Unlike a scanning dispersive spectrometer, which possesses a single exit slit, the Hadamard transform (HT) spectrometer employs a multislit array as a Hadamard encoding mask. This arrangement allows for the simultaneous measurement of a multitude of spectral resolution elements at a single-element detector and produces a multiplexing spectrometer.

Theory of Hadamard Multiplexing

The operation of the HT spectrometer can be described using matrix algebra with column vectors [**D**] and [**I**] and the N-order square matrices $\mathbf{S}_N$, $\mathbf{S}_N^{-1}$, $\mathbf{S}_N^{\mathrm{T}}$, and $\mathbf{T}_N$. [**D**] is a column vector of N rows containing the detector responses for the N encodements. [**I**] is a column vector of N rows containing the N spectral resolution elements to be determined. $\mathbf{S}_N$ is the cyclic **S** matrix of order N that is the basis for construction and design of the Hadamard encoding mask. $\mathbf{S}_N^{-1}$ is the inverse of $\mathbf{S}_N$ and is given by $(2/(N+1))\mathbf{T}_N$. $\mathbf{T}_N$ is a matrix of $+1$ and -1

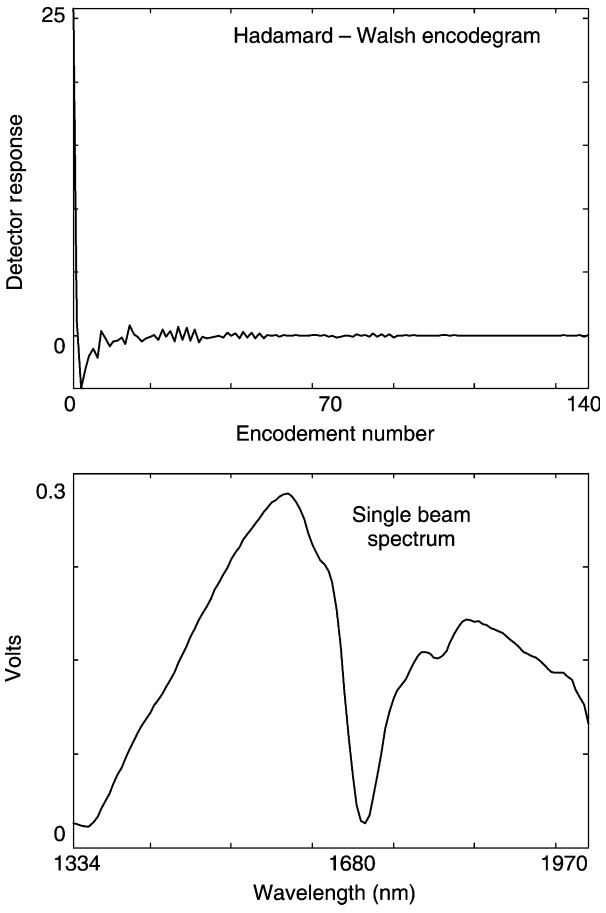

Figure 2 An encodegram (top plot) and the corresponding single-beam spectrum (bottom plot) as a result of decoding the encodegram using Hadamard mathematics.

elements obtained from $\mathbf{S}_N^T$, the transpose of $\mathbf{S}_N$, with $\mathbf{T}_N$ having +1's and −1's where $\mathbf{S}_N^T$ has 1's and 0's, respectively. A cyclic matrix is required to be symmetric so that an interchange of columns and rows can recover the original matrix and $\mathbf{S}_N^T$ then becomes equal to $\mathbf{S}_N$. The encoding of the radiation by the HT spectrometer is given by $[\mathbf{D}] = \mathbf{S}_N[\mathbf{I}]$ and the resulting primary data are a record of detector response versus encodement number. The plot of detector response versus encodement number is called an encodegram (analogous to the interferogram produced by an FT spectrometer). The decoding of the encodegram to recover the conventional spectrum using a Hadamard transform can be described by $[\mathbf{I}] = \mathbf{S}_N^{-1}[\mathbf{D}]$, obtained by left multiplying $[\mathbf{D}] = \mathbf{S}_N[\mathbf{I}]$ by $\mathbf{S}_N^{-1}$. In practice, it is not necessary to invert $\mathbf{S}_N$ because there is a fast Hadamard transform (FHT) algorithm available when N is of the form $N = 2^w - 1$, w being an integer. There are three known methods for generating the first row of cyclic S matrices of order $N = 2^w - 1$. Consider the example of $N = 7$ for $w = 3$ where the first row of $\mathbf{S}_7$ is 1 1 1 0 1 0 0. Figure 2 shows an encodegram and the result of decoding using Hadamard mathematics. Figure 3 contains the matrices and matrix equations for $N = 7$.

Hadamard Encoding Masks

The key component of any HT spectrometer is the Hadamard encoding mask (Figure 4). Two choices for the Hadamard encoding mask are the moving mechanical mask and the stationary electro-optical mask. The moving mask for N spectral resolution elements requires $2N - 1$ mask elements that are either completely open with a transmittance of 1 or completely closed with a transmittance of 0. The stationary mask for N spectral resolution elements requires only N mask elements that are selected to be either transparent: transmittance $T_t = 1$ or <1 or opaque: transmittance $T_o = 0$ or >0. The resulting SNR is dependent upon $\Delta T = T_t - T_o$, which has its optimal value of unity only for an ideal mask which is $T_t = 1$, $T_o = 0$. The advantage of the moving mask is

$$
[D] = \begin{matrix} D_1 \\ D_2 \\ D_3 \\ D_4 = \\ D_5 \\ D_6 \\ D_7 \end{matrix}
\begin{matrix} I_1 + I_2 + I_3 + I_5 \\ I_1 + I_2 + I_4 + I_7 \\ I_1 + I_3 + I_6 + I_7 \\ I_2 + I_5 + I_6 + I_7 \\ I_1 + I_4 + I_5 + I_6 \\ I_3 + I_4 + I_5 + I_7 \\ I_2 + I_3 + I_4 + I_6 \end{matrix}
\qquad
S_7 = \begin{matrix} 1\,1\,1\,0\,1\,0\,0 \\ 1\,1\,0\,1\,0\,0\,1 \\ 1\,0\,1\,0\,0\,1\,1 \\ 0\,1\,0\,0\,1\,1\,1 \\ 1\,0\,0\,1\,1\,1\,0 \\ 0\,0\,1\,1\,1\,0\,1 \\ 0\,1\,1\,1\,0\,1\,0 \end{matrix}
\qquad
[I] = \begin{matrix} I_1 \\ I_2 \\ I_3 \\ I_4 \\ I_5 \\ I_6 \\ I_7 \end{matrix}
$$

$$
T_7 = \begin{matrix} 1\,1\,1\,{-1}\,1\,{-1}\,{-1} \\ 1\,1\,{-1}\,1\,{-1}\,{-1}\,1 \\ 1\,{-1}\,1\,{-1}\,{-1}\,1\,1 \\ {-1}\,1\,{-1}\,{-1}\,1\,1\,1 \\ 1\,{-1}\,{-1}\,1\,1\,1\,{-1} \\ {-1}\,{-1}\,1\,1\,1\,{-1}\,1 \\ {-1}\,1\,1\,1\,{-1}\,1\,{-1} \end{matrix}
\qquad
S_7^{-1} = (1/4)T_7 = \begin{matrix} (1/4)(1\,1\,1\,{-1}\,1\,{-1}\,{-1}) \\ (1/4)(1\,1\,{-1}\,1\,{-1}\,{-1}\,1) \\ (1/4)(1\,{-1}\,1\,{-1}\,{-1}\,1\,1) \\ (1/4)({-1}\,1\,{-1}\,{-1}\,1\,1\,1) \\ (1/4)(1\,{-1}\,{-1}\,1\,1\,1\,{-1}) \\ (1/4)({-1}\,{-1}\,1\,1\,1\,{-1}\,1) \\ (1/4)({-1}\,1\,1\,1\,{-1}\,1\,{-1}) \end{matrix}
$$

$$
[I] = \begin{matrix} I_1 \\ I_2 \\ I_3 \\ I_4 \\ I_5 \\ I_6 \\ I_7 \end{matrix}
= S_7^{-1}[D] =
\begin{matrix} (1/4)(\,D_1 + D_2 + D_3 - D_4 + D_5 - D_6 - D_7\,) \\ (1/4)(\,D_1 + D_2 - D_3 + D_4 - D_5 - D_6 + D_7\,) \\ (1/4)(\,D_1 - D_2 + D_3 - D_4 - D_5 + D_6 + D_7\,) \\ (1/4)(-D_1 + D_2 - D_3 - D_4 + D_5 + D_6 + D_7\,) \\ (1/4)(\,D_1 - D_2 - D_3 + D_4 + D_5 + D_6 - D_7\,) \\ (1/4)(-D_1 - D_2 + D_3 + D_4 + D_5 - D_6 + D_7\,) \\ (1/4)(-D_1 + D_2 + D_3 + D_4 - D_5 + D_6 - D_7\,) \end{matrix}
$$

For example: Note $I_1 = (1/4)\,[\,(D_1 + D_2 + D_3 + D_5\,) - (D_4 + D_6 + D_7\,)\,]$ so

$$
I_1 = (1/4)\,\{\,[\,(I_1 + I_2 + I_3 + I_5\,) + (I_1 + I_2 + I_4 + I_7\,) + (I_1 + I_3 + I_6 + I_7\,) + (I_1 + I_4 + I_5 + I_6\,)\,] - [\,(I_2 + I_5 + I_6 + I_7\,) + (I_3 + I_4 + I_5 + I_7\,) + (I_2 + I_3 + I_4 + I_6\,)\,]\,\} = (1/4)\,\{\,4I_1\,\} = I_1
$$

Figure 3 Matrices and matrix equations (note since $\mathbf{S}_7$ is symmetric $\mathbf{S}_7^T = \mathbf{S}_7$).

Figure 4 A linear encodement of length $N = 43$ generated by using a quadratic residue construction.

no optical transmission problems. However, it suffers the disadvantage of having moving parts and position repeatability problems. For the case of the stationary mask, it has the advantage that it has no moving parts and no positioning repeatability problems. The disadvantage of the stationary mask is the optical transmission problem where $T_t < 1$ and $T_o > 0$. The moving Hadamard encoding mask of $2N - 1$ mask elements is changed to the next encodement by translation of the Hadamard encoding mask to the left past the aperture by a single mask element. For $N = 7$ and $2N - 1 = 13$, the assignment of 1 and 0 to positions 1 through 13 is [1 1 1 0 1 0 0 1 1 1 0 1 0]. For example, the first encodement corresponding to the first row of S_7 in Figure 3 is from positions 1 through 7 as [1 1 1 0 1 0 0] and the fourth encodement corresponding to the fourth row of S_7 in Figure 3 is from positions 4 through 10 as [0 1 0 0 1 1 1].

2D Encoding Masks for Multiplexing in Spectral Imaging and Imaging

If the conventional one-dimensional (1D) Hadamard encoding mask is folded in some manner, the result is the generation of a two-dimensional (2D) Hadamard encoding mask (Figure 5). Similar to the 1D Hadamard encoding masks that are used for spectral mutiplexing, 2D Hadamard encoding masks can be used for the spatial multiplexing done in Hadamard transform spectral imaging (HTSI) and Hadamard transform imaging (HTI). It is important to note that spectrometry as HTS, spectral imaging as HTSI, and imaging as HTI all realize the same theoretical SNR improvement based on the number of spectral, spatio-spectral, or spatial resolution elements (N), respectively. Consider the folding of a 1D Hadamard encoding mask for $N = 15$ into a 2D Hadamard encoding mask of three rows and five columns (Figure 6). A cyclic S_{15} has a first row of [0 0 0 1 0 0 1 1 0 1 × 0 1 1 1 1] so the 2D Hadamard encoding mask has a first row of [0 0 0 1 0], a second row of [0 1 1 0 1], and a third row of [0 1 1 1 1] from columns 1 through 5, 6 through 10 and 11 through 15, respectively, from S_{15}.

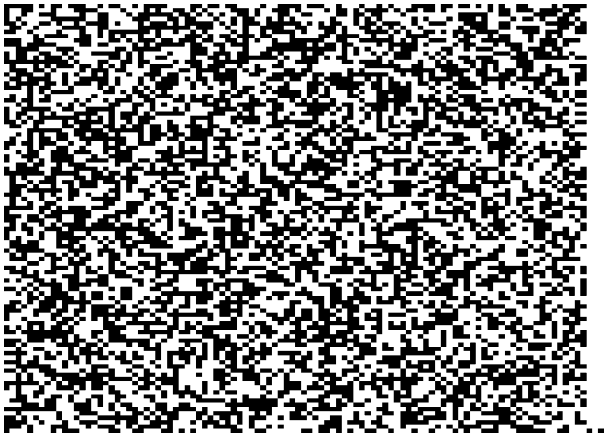

Figure 5 A two dimensional encodement of length $N = 10{,}007$ in a 100×100 format generated by quadratic residue construction. The remaining 7 elements are shown as the last 7 elements in the bottom row on the right. In practice these 'extra' data points can be masked off and used as a measure of system noise characteristics.

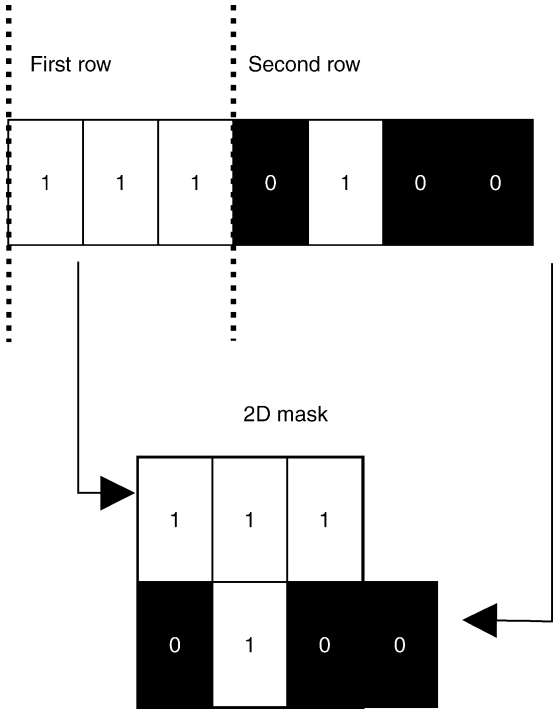

Figure 6 Spectrometry to imagery: The folding of a ID encoding mask that can be used for spectrometry is used to generate a 2D encoding mask that can be used for imaging. Note that using a symmetric aperture window where only 3×2 elements are used, the mask element that is not included in the windowed aperture can be used as a measure of the dark noise of the system, however, a more conventional encodement matrix might be one that can be divided into an integer number of rows and columns such as $N = 15$ where one can construct a 5×3 2D encodement mask for imagery and use a symmetric aperture that uses the entire length of the encodement matrix.

Hadamard Mathematics

Consider a general multiplexing problem where one seeks to measure N quantities, $X = \{x_0, x_1, \ldots, x_{N-1}\}$, in the presence of noise, and wishes to determine a vector function $F(X)$, such that the measurement of $F(X)$ yields the best estimate of X. Conservation of energy and superposition principles dictate a restriction to linear functions. The principle of rank suggests that we restrict our measurements to N-dimensional linear combinations. Determining the best linear combination is the challenge. In the case of constant error for each measurement, an answer is provided by Hotelling's theorem, which proves Hadamard matrices are optimal for such measurements. Hadamard matrices uniquely achieve the optimal bound for root-mean-square measurement error. A Hadamard matrix is a matrix $\mathbf{H}$ for which $\mathbf{H}_{i,j} = \pm 1$, and $\mathbf{H}^{-1} = \frac{1}{N}\mathbf{H}^{\mathrm{T}}$. The definitions of matrix inverse, transpose, and multiplication dictate that the rows of the matrix $\mathbf{H}$ form an orthogonal basis with each basis element having norm $\sqrt{N}$. The norms of the rows of $\mathbf{H}$ follow from the entries of the matrix that are ± 1, and place no additional restriction on $\mathbf{H}$. The columns of $\mathbf{H}$ are also an orthogonal basis with these same norms. The rows (columns) of the matrix $\frac{1}{\sqrt{N}}\mathbf{H}$ form an orthonormal basis. From these few statements and definitions, one can already derive estimates of the multiplex advantage. For example, one seeks to measure X and in one case measures $Y_1 = X + \varepsilon$, where ε is a random noise or error that has a Gaussian distribution with a mean of 0 and variance σ^2. In another case, suppose that one measures $Y_2 = HX + \varepsilon$. In this second case, one would estimate

$$X_2 = \frac{1}{N}\mathbf{H}^{\mathrm{T}}(\mathbf{H}X + \varepsilon) = X + \left(\frac{1}{\sqrt{N}}\right)^2 \mathbf{H}^{\mathrm{T}}\varepsilon$$
$$= X + \frac{1}{\sqrt{N}}\varepsilon_1$$

where ε_1 is random noise with the same characteristics as ε. It follows that the measurement error in the second case has a standard deviation σ that is less than in the former case, with an improvement by the factor $\frac{1}{\sqrt{N}}$.

Hadamard Computations

The ± 1 Hadamard matrices can be applied to two detector optical systems, and 0,1 matrices can be applied to single detector systems. In a two detector system $\mathbf{H}^{\mathrm{T}}$ is proportional to $\mathbf{H}^{-1}$ and one can invert these transforms. Suppose that one has chosen a particular Hadamard matrix $\mathbf{H}$, with which to conduct a multiplexed measurement. One can show that multiplication of any row or any column by -1 does not affect the efficacy of $\mathbf{H}$ in improving SNR. Hence one may assume that the first row and first column of $\mathbf{H}$ are all $+1$. From $\mathbf{H}$, we can form a new $(N-1)\times(N-1)$ matrix $\mathbf{S}$ by deleting the first row and column of $\mathbf{H}$, and then changing each 1 to a 0, and each -1 to a 1. This new matrix $\mathbf{S}$, an $\mathbf{S}$-matrix, is the one corresponding to $\mathbf{H}$ that is to be used for single-element detector optical systems. It is known that $\mathbf{S}$ matrices are optimal for 0,1 matrices just as Hadamard matrices are optimal for ± 1 matrices, with signal to noise improvement by a factor $\frac{\sqrt{N-1}}{2}$, where here N is the dimension of $\mathbf{H}$.

Letting $\mathbf{I}$ be the identity matrix, and $\mathbf{J}$ be the matrix whose entries are all 1, it follows that $\mathbf{S}^{\mathrm{T}}\mathbf{S} = \frac{N}{4}(\mathbf{I} + \mathbf{J})$, where N is the dimension of $\mathbf{H}$. From this we can ascertain that a multiplexed system using the matrix $\mathbf{S}$, multiplied by the encoded parameters of $\mathbf{S}^{\mathrm{T}}$ recovers the original signal to within the addition of an offset. In practice this is what is done to recover the original X. In certain cases, there is also a fast algorithm for computing $\mathbf{S}^{\mathrm{T}}Y$, without ever explicitly computing $\mathbf{S}^{\mathrm{T}}$.

Constructions for Hadamard Matrices

It is known that if $\mathbf{H}$ is an $N \times N$ Hadamard matrix, then N must be 1, 2, or a multiple of 4 and so nontrivial $\mathbf{S}$-matrices must be of size one less than a multiple of 4. It is conjectured that Hadamard matrices exist for each N which is a multiple of 4. Some constructions of Hadamard matrices are enumerated below.

Walsh–Hadamard Construction

A Hadamard matrix of size $N = 2^K$ can be constructed by sampling the first N Walsh functions at $0, 1/N, 2/N, 3/N, \ldots, (N-1)/N$, where the Walsh functions are defined by $W_0(x) = 1$, for $0 \le x < 1$, $W_0(x) = 0$ otherwise, and the recurrence relations, for each non-negative integer n:

$$\begin{aligned} W_{2n}(x) &= W_n(2x) + W_n(2x-1), \text{ and} \\ W_{2n+1}(x) &= W_n(2x) - W_n(2x-1) \end{aligned} \qquad [1]$$

Tensor Product Construction

Walsh is a special case of iterating this construction, starting with the matrix $\mathbf{H}_1 = [1]$. In general, if $\mathbf{H}_N$ is

a Hadamard matrix of size $N \times N$, then:

$$\mathbf{H}_{2N} = \begin{bmatrix} H_N & H_N \\ H_N & -H_N \end{bmatrix} \qquad [2]$$

is a Hadamard matrix of size $2N \times 2N$.

Quadratic Residue Construction

This construction is an example of a cyclic **S**-matrix: one for which each row is a cyclic shift of the previous row. Given a prime number $p = 4n + 3$, define, for $i = 0, \ldots, p - 1$, the values $\mathbf{S}_{1,i} = 1$ if there is some integer k, such that the remainder of dividing k^2 by p is i, and $\mathbf{S}_{1,i} = 0$ otherwise. Taking the cyclic matrix with the first row given by $\mathbf{S}_{1,i}$, yields a Hadamard **S**-matrix.

Other constructions are possible. Maximal length shift register codes, and a construction involving quadratic residues of twin primes are two examples.

Fast Hadamard Transforms

The fast Walsh transform can be deduced from eqn [1]. The basic idea is that, in eqn [1], the function W_n is specified by $\log_2 n$ recurrence relations. For this reason, a Walsh transform (or its transpose) can be computed in $O(n \log_2 n)$ steps. The algorithm goes as follows, for a sequence of length $N = 2^n$:

(i) begin with $Y_{0,0}, Y_{0,1}, \ldots, Y_{0,N-1} = Y_0, Y_1, \ldots, Y_{N-1}$
(ii) for $i = 1, \ldots, n - 1$, let $Y_{i,k} = Y_{i-1,2k} + Y_{i-1,2k+1}$, and $Y_{i,n/2+k} = Y_{i-1,2k} - Y_{i-1,2k+1}$, for $k = 0, \ldots, N/2$
(iii) output $X_i = Y_{n-1,i}$

Then the resulting X_i is the inverse Walsh transform of Y_i.

Note that cyclic **S** matrices that come from maximal length shift registers are known to be permutations of the Wzalsh–Hadamard **S** matrices, and hence there is also a fast algorithm for inverting these, albeit involving some tedious permutations.

Optics for Hadamard Encoded Apertures

Hadamard optical systems utilize spatially encoded apertures that can be employed either at the entrance aperture of the optical system, the exit aperture or both. They have the common attribute that they encode the available aperture spatially where the spatial resolution elements that make up the encodement dictate the spectral, spatio-spectral, or spatial resolution elements that propagate through the optical system, including diffractive optical elements and on to the sensor or exit aperture. These masks have some spatial extent that places special requirements on the optics of the system. As the encodement mask grows either by longer length encodements with fixed subapertures or as the subaperture dimension grows for a fixed encodement length, the spatial resolution elements making up the subapertures in the encodement mask depart from the optical axis. When the resolution elements depart from the optical axis or paraxial condition, it becomes important to employ optics that can image the off-axis resolution elements without inducing excessive aberrations that degrade the performance and cripple the advantages gained by HT multiplexing.

Typically the optical path for conventional monochromators begins with a source that is focused onto an aperture plane that has a large aspect ratio aperture know as a slit. This slit is often very small in extent in the dispersion plane compared to the other extent in the spatial plane. However, it is not required that this aspect ratio is large. If the aspect ratio is close to 1 then simple spherical optics can be employed that perform well as long as the departure from the optical axis is kept to a minimum. However, most monochromators have a large aspect ratio in order to increase the opportunity to maximize throughput, and detectors must be able to 'see' the large extent of the slit aperture. The light entering the slit aperture is then dispersed and focused onto an exit slit aperture. Monochromators are only required to perform well on the optical axis and do not typically employ optics that can manage rays that depart from the optical axis in the plane of dispersion as required by HT multiplexing instruments. To employ encoding techniques the optical system is required to utilize optical performance attributes normally found only in imaging and spectral imaging systems. This requirement is driven by the extent of the encoding mask. The extent of the encoding mask is governed by the diffraction limit of the wavelengths within the bandpass, the encodement length N, and the attributes of the optical system.

In a conventional dispersive spectrometer the radiation from a source is collected and separated into its individual spectral resolution elements by a spectral separator such as a diffraction grating or prism and then is collected and focused for spatial

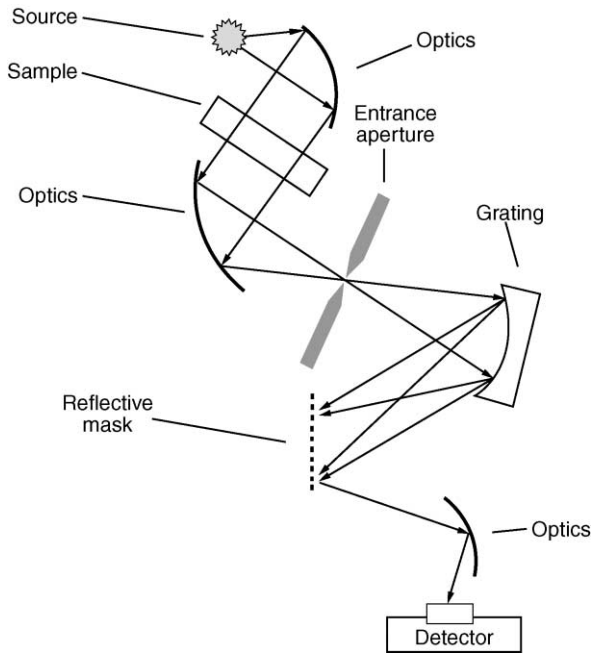

Figure 7 Example implementation of a Hadamard transform spectrometer with reflective optics. Light from a source passes through a sample, is transferred into an entrance aperture, bounced off of a concave grating, and then a reflective mask, and finally transferred to a detector.

presentation on a focal plane. The dispersive spectrometer uses a single exit slit to select one spectral resolution element at any given time, out of N possible spectral resolution elements for measurement by the detector. The Hadamard transform spectrometer (HTS, Figure 7) uses an array of slits (i.e., a mask) at the focal plane to select one more than half, $(N + 1)/2$, of the spectral resolution elements at the focal plane for measurement by the detection system. The optical challenge to effect an HT multiplexing spectrometer is to collect all of the spatially distributed individual bandpass images of the entrance slit and transfer them to as small a detector as possible. One desires to keep the area of the detector at a minimum as the noise of many detectors increases with the square of the area. If the optics are able to illuminate a single detector element with all of the available light impinging upon the focal plane containing the spatially distributed images of the slit for each of the N bandpass resolution elements, a multitude of spectral resolution elements can be measured simultaneously using a single detector element. This arrangement results in a multiplexing spectrometer. The recovery of N spectral resolution elements requires measuring the detector response for N different encodements of $(N + 1)/2$ open mask elements. The raw data are recorded as the detector response versus encodement number and is called an encodegram. Hadamard transformation of the encodegram yields the spectrum.

The History of Applied Hadamard Multiplexing

The Hadamard transform instruments developed in the 1960s and 1970s employed moving masks. Significant problems such as misalignment and jamming associated with a moving mask led to a reputation of poor reliability and contributed to a dormant period in the development of HTS and HTI. Interest was rekindled in the 1980s using stationary Hadamard encoding masks based on liquid crystal (LC) technology. The first generation 1D stationary Hadamard encoding mask was a cholesteric LC with $N = 127$ mask elements and used polarization as its operating phenomenon. Two parallel polarizers and rotation or lack of rotation of the polarized radiation generated the opaque and transparent states, respectively. The second generation 1D stationary Hadamard encoding mask was fabricated using a polymer dispersed liquid crystal (PDLC) material with $N = 255$ mask elements and used light scattering as its operating phenomenon. The PDLC contained LC droplets dispersed in a polymer matrix whose index of refraction matched the index of refraction in one direction in the birefringent LC droplet. Alignment of the LC droplets optical axis under an applied voltage removed discontinuities in index of refraction at the polymer matrix/LC interface to generate a good transparent state while random orientation of LC droplets in the polymer matrix generated the opaque state from light scattering by the discontinuities in index of refraction at the polymer matrix/LC droplet interface. A 2D stationary Hadamard encoding mask was also based on LC technology. A ferro-electric liquid crystal positioned between a pair of polarizers with perpendicular orientation operated as an electro-optic half-wave plate when a +value of applied voltage rotated the plane of polarization by 90 degrees to produce the transparent state and a −value of applied voltage left the plane of polarization unaltered to produce the opaque state.

Development based on stationary Hadamard encoding masks continued in the 1990s and a 2D moving Hadamard encoding mask was also fabricated and used to perform imaging in the near-infrared and mid-infrared spectral regions. Note that the mid-infrared spectral region is not generally accessible via Hadamard encoding masks based on

LC technology, since any LC material is expected to have strong absorption bands in the mid-infrared spectral region. From the mid-1990s to the present, the stationary Hadamard encoding mask of choice for the visible and near-infrared spectral regions has been the digital micromirror device (DMD), a device based on micro-optoelectromechanical systems (MOEMS) technology and developed by Texas Instruments for projector display applications. One DMD format incorporates 508 800 micromirrors in an 848 column by 600 row array that is 14.4 mm wide by 10.2 mm high. Each individual micromirror is 16 μm square and adjacent micromirrors are separated by a 1 μm gap. The micromirrors are individually addressable and rotate by +10 or −10 degrees about the diagonal axis to produce binary 'on' and 'off' states. The on state has T_t determined by the mirror reflectivity and approaches 1 while the off state approaches $T_o = 0$. The ideal condition of on and off is not realized due to diffraction of the light off of the small and periodic features of the micromirror device. The DMD is an array of spatial resolution elements that may be selected as groups of super-resolution elements or as individual resolution elements consisting of a single micromirror. The DMD resolution elements are realized as spectral resolution elements in the spectrometer with the columns attributed to the frequency or wavelength dimension and the rows attributed to the slit height dimension. The DMD resolution elements are utilized as spatio-spectral resolution elements in the imaging spectrograph with the columns as the frequency or wavelength dimension and the rows as a vertical spatial dimension with the horizontal spatial dimension being accessed, if desired, by translating the sample relative to the imaging spectrograph. The DMD resolution elements are spatial resolution elements in the imager with the columns for the horizontal dimension and the rows for the vertical dimension and the frequency or wavelength dimension provided by other instrumentation. If a photo-acoustic detection system is present then the depth dimension of the sample may also be accessed by changing the modulation frequency used in the photo-acoustic detection system.

Some important features of HTS to keep in mind are:

(i) it is a dispersive technique using a spectral separator;
(ii) it is a multiplexing technique using a single-element detector;
(iii) it uses a Hadamard encoding mask (multislit array) in a focal plane;
(iv) it sends one more than half the resolution elements to the single-element detector in each encodement;
(v) it uses a number of encodements equal to the number of resolution elements desired and the number of mask elements (pixels) in the stationary Hadamard encoding mask (a moving Hadamard encoding mask has $2N - 1$ mask elements);
(vi) it has each encodement containing a different combination of one more than half the resolution elements;
(vii) it has as its primary data the encodegram, a record of detector response versus encodement number; and
(viii) it uses a FHT of the encodegram to decode the encodegram and generate the spectrum or image.

Note that all of these, except for item (i), also apply to HTSI and HTI. The DMD promises to be the best Hadamard encoding mask yet developed for the visible and near-infrared spectral regions. However, its potential applications in spectrometry and imaging are by no means limited to HT techniques since the information corresponding to any micromirror in the DMD may be included in or excluded from any measurement as desired by the investigator. An instrument with no moving parts, other than the micromirrors in the DMD, promises to provide a compact and robust instrument for operation in potentially hostile environments ranging from process control to outer space. It is our belief that the combination of a DMD with a single-element detector may provide an important advance in spectroscopic instrumentation and that instrumentation based on the DMD may lead to a host of environmental, industrial, medical, and military applications.

Introduction: Linear and Nonlinear Spectroscopy

Light propagates in transparent or weakly absorbing media by inducing the atoms or molecules in the material to oscillate in response to the electromagnetic field of the light. The induced dipole oscillations set up a polarization field **P** which radiates the wave in the propagation direction. The induced polarization **P** is proportional to the amplitude of the electric field **E** in the incident light:

$$\mathbf{P} = \varepsilon_0 \chi^{(1)}(\omega)\mathbf{E} \qquad [1]$$

where ε_0 is the permittivity of free space and $\chi^{(1)}(\omega)$ is the first-order, frequency-dependent, susceptibility of the material. This interaction of the light with the medium generally results in some absorption of energy from the field and a shift in the phase of the propagating light. Both the phase delay and the absorption depend on the frequency ω (and wavelength λ) of the light. The phase shifting is responsible for dispersion – the variation, as a function of frequency, of the speed (phase velocity) of light in the medium. The dispersion and absorption effects are described by the real and imaginary parts, respectively, of the complex susceptibility:

$$\chi(\omega) = \chi_{\mathrm{Re}}(\omega) + \mathrm{i}\chi_{\mathrm{Im}}(\omega) \qquad [2]$$

This susceptibility parameter describes the optical properties of the medium. Linear spectroscopy uses the frequency-dependent property of the $\chi(\omega)$ to create spectra by absorption or dispersion of specific frequencies that are resonant with transitions between internal energy states of the molecules. The electric field in the incident light is considered to be weak when it leaves the atomic and molecular properties essentially unaffected. Nonlinear optical spectroscopy, however, is based on the ability of intense laser light to modify the optical properties of the medium through which it propagates. These effects are also frequency dependent and so can be used to generate spectra. When the strength of the electric field becomes comparable with the electric fields within the atoms or molecules (typically $\sim 10^{11}\,\mathrm{V\,m^{-1}}$) then the induced polarization becomes nonlinear and is described by a power series expansion:

$$\mathbf{P} = \varepsilon_0[\chi^{(1)}(\omega)\mathbf{E}_1 + \chi^{(2)}(\omega)\mathbf{E}_1\mathbf{E}_2 + \chi^{(3)}(\omega)\mathbf{E}_1\mathbf{E}_2\mathbf{E}_3 + \text{higher-order terms}] \qquad [3]$$

$\chi^{(2)}(\omega)$ and $\chi^{(3)}(\omega)$ are the second- and third-order susceptibilities respectively. The real and imaginary parts of these susceptibilities (and of the higher-order terms) describe observable effects arising from absorption and dispersion. The associated interactions involve two and three photon processes, respectively. In general, nonlinear interactions involve multiphoton processes and will be described by the appropriate term in the expansion of the induced polarization.

Broadly speaking, nonlinear spectroscopy is based on detection of these multiphoton interactions by either incoherent or coherent processes. Incoherent processes include fluorescence and ionization where, following the multiphoton interaction, photons or electrons respectively are emitted spontaneously in all directions. Coherent processes, on the other hand, arise from the coupling of the input driving fields via the nonlinear polarization of the medium.

The waveform of the polarization oscillations is a distorted form of the driving field. Fourier analysis of these nonlinear oscillations would reveal extra frequencies not present in the incident field. When a suitably phased array of dipoles is established, the nonlinear optical process is detected by emission of coherent directional light. The efficiency with which this coherent signal beam is generated is crucially dependent upon the correct phasing of the radiating molecules. This process is known as phase matching and is achieved by geometrical arrangements of the input beams or by modifying the refractive index to counteract dispersion between the generating polarization wave and the radiated signal wave.

Apart from the general division of nonlinear spectroscopy according to whether the detection uses incoherent or coherent emission, the techniques are characterized as frequency or time domain methods, according to how the signal is generated and detected. In most cases the signals recorded in either domain may be related by a Fourier transformation to an equivalent signal in the other.

The advantages of nonlinear spectroscopic techniques lie in their ability to provide high spectral, temporal, and spatial resolution. In particular, it is possible, using a variety of nonlinear optical processes, to eliminate inhomogeneous broadening of the spectral lines recorded. Second, when coherent signal beams are generated they can be readily distinguished from incoherent background emissions, thus permitting high signal-to-noise ratios. Third, the use of short laser pulses, down to the order of 10^{-15} s, allows high temporal resolution. High spatial resolution is achieved by generating signals from interaction regions defined by crossed and focused beams. Although the coefficients of successive terms in the power series expansion of the nonlinear polarization decrease by many orders of magnitude with increasing order, signal strengths may be made comparable to those of linear spectroscopy. Strong signals are obtained by the use of resonant enhancement of the nonlinear susceptibility, high field strengths from laser sources, and the use of sensitive photodetectors.

Second-Order Nonlinear Effects

Weak light fields leave unaffected the optical properties of the medium through which they propagate. When, however, the second-order susceptibility $\chi^{(2)}$ contributes significantly to the induced polarization, the complex refractive index includes a field-dependent term:

$$\mathbf{P} = \varepsilon_0[\chi^{(1)}(\omega) + \chi^{(2)}(\omega)\mathbf{E}_1]\mathbf{E}_2 \qquad [4]$$

Owing to the symmetry properties of $\chi^{(2)}$, second-order nonlinear effects are absent in isotropic media or those possessing a center of inversion symmetry. They may, however, be observed in anisotropic materials such as crystalline solids where they are the basis of frequency mixing schemes leading to second-harmonic generation, sum- and difference-frequency generation, and optical parametric amplification and oscillation. The symmetry of gas phase media, such as atomic vapors, may be broken by application of an external electric or magnetic field. Resonantly enhanced second-harmonic generation has been achieved in alkali metal vapors in the presence of a magnetic field giving potential for spectroscopy. Symmetry breaking is achieved also on solid surfaces where sum-frequency generation has been used to study surface morphology, monatomic layers, and catalytic effects of adsorbed materials.

Third-Order Nonlinear Spectroscopy

In gas phase or isotropic solid and liquid media, the first nonlinear term is of third order and leads to a refractive index that is dependent on the field intensity $|\mathbf{E}|^2$:

$$\mathbf{P} = \varepsilon_0[\chi^{(1)}(\omega) + \chi^{(3)}(\omega)\mathbf{E}^2]\mathbf{E} \qquad [5]$$

Intensity-dependent refractive index effects lead to a wide range of nonlinear optical phenomena. In general, the polarization contains terms that are the product of three input fields generating Fourier components at sum and difference frequencies. Phase matching constraints will generally determine which of the possible interactions will be observed. A wide range of physical effects contribute to $\chi^{(3)}(\omega)$. The simplest of these nonlinear effects is saturation of the absorption.

Linear absorption is defined by the situation where the intensity decays exponentially with propagation distance x, according to Beer's Law:

$$I(x) = I(0)\exp\{-\alpha_0(\omega)x\} \qquad [6]$$

where $I(0)$ and $I(x)$ are the intensity values at $x = 0$ and x, respectively, and $\alpha_0(\omega)$ is the weak field absorption coefficient. The fractional power absorbed in this case is, therefore:

$$[I(0) - I(x)]/I(0) = \alpha_0(\omega)x \qquad [7]$$

and is independent of the intensity. When the incident intensity increases, until the rate of stimulated absorption from the lower level equals the spontaneous emission rate out of the upper level, the medium is said to be saturated. The intensity is

then I_{sat}. A simple rate-equation analysis shows that the absorption coefficient in the presence of a strong light field is:

$$\alpha(\omega) = \frac{\alpha_0(\omega)}{[1 + I/I_{sat}]} \qquad [8]$$

The absorption is then no longer independent of the light intensity.

Saturation Spectroscopy

In the case of a homogeneously broadened transition the effect of a saturating monochromatic light field is to reduce the absorption across the entire line profile. This is shown in Figure 1a where the frequency of the incident light w_L is detuned from line center ω_0. The degree of saturation and the effect on the absorption coefficient depends on the intensity I and the detuning $\Delta\omega = \omega_L - \omega_0$.

For a transition dominated by inhomogeneous broadening a monochromatic light field interacts strongly only with a sub-group of atoms. This sub-group is determined by those having a resonance frequency within the spectral range covered by the homogeneous width and centered on the incident frequency. Saturation in this case results in 'hole burning' as shown in Figure 1b. A dip in the absorption coefficient $\alpha(\omega)$ is produced centered on ω_L of width given by the homogeneous width.

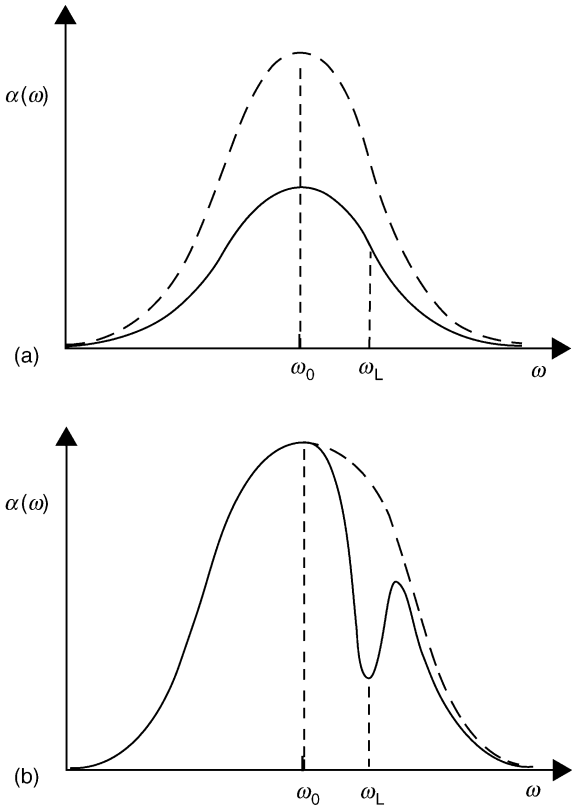

Figure 1 Absorption lineshapes for (a) homogeneously broadened and (b) inhomogeneously broadened lines centered at ω_0. Dashed lines in both figures show lineshape measured by weak probe. Solid lines show lineshape measured by weak probe in presence of a monochromatic, saturating beam at frequency $\omega_L \neq \omega_0$.

Saturation affects the population of both upper and lower levels involved in an optical transition and so affects both absorption and amplification (gain). The phenomenon shows itself as a narrow dip in the spectral profile of lasers operating on an inhomogeneously broadened gain line (e.g., a HeNe gas laser). These 'Lamb dips', as they are called, are the result of saturation by the laser mode which has a very narrow spectral width. Only those atoms in the Maxwell–Boltzmann velocity distribution are saturated, whose velocity results in a Doppler shift of the light that brings it into resonance, i.e., to within the atom's homogeneous linewidth of the resonance frequency. When the laser mode frequency is detuned from atomic line center two velocity subgroups of atoms, within the distribution, are saturated corresponding to positive and negative Doppler shifts for counter-propagating fields of the mode. When the mode frequency is tuned to atomic line center, the counter-propagating fields interact with the same (zero) velocity subgroup. The saturation effect is thereby enhanced, reducing the gain by depletion of the population inversion, leading to a dip in output intensity at line center. The width of the dip is the homogeneous width of the transition (Figure 2).

The variation of output intensity around the Lamb dip is used to provide an error signal in one scheme for laser frequency stabilization. A feedback system is employed to adjust the cavity length, L, in order to maintain the mode frequency, ν, exactly on atomic line-center ($\nu = mc/2L$ where m is an integer). This scheme uses gain saturation of the amplifying medium, whereas an alternative uses saturated absorption. In this scheme, a cell of gas having a narrow absorption line, within the gain profile of the laser, is placed inside the cavity. When the laser mode is tuned to absorption, line-center saturation reduces the absorption loss, resulting in a narrow peak in the laser emission. Drifting off this peak can be used as an error signal, as before, to stabilize the mode frequency.

Saturated absorption spectroscopy uses the same mechanism by placing the absorbing specimen outside the laser cavity. The effect is detected by monitoring the transmission of a weak probe beam in the presence of a strong counter-propagating 'pump' beam. Both probe and pump beams are

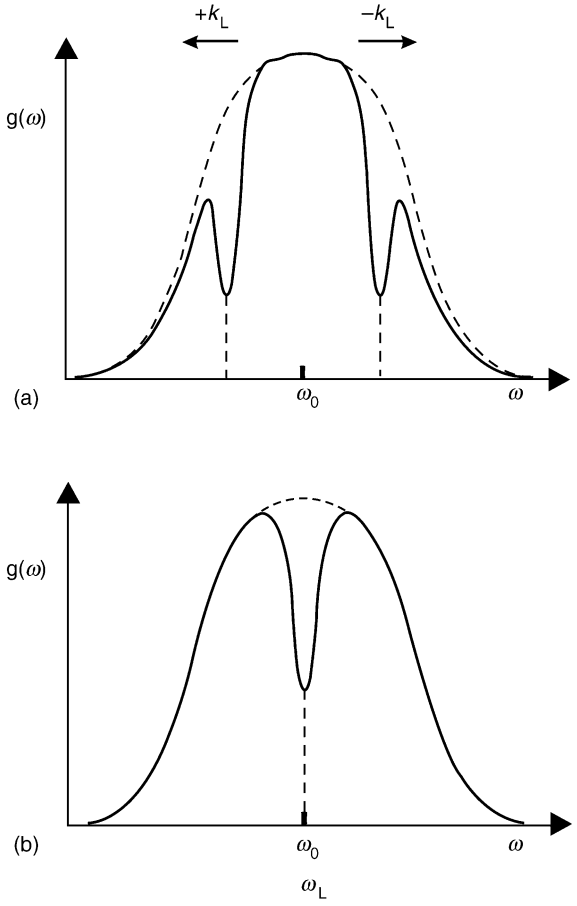

Figure 2 (a) Holes burned in gain profile by two counter-propagating monochromatic waves at $\omega_L \neq \omega_0$. (b) 'Lamb dip' in gain profile $g(\omega)$ (or absorption profile $\alpha(\omega)$) when $\omega_L = \omega_0$.

derived from the same laser using a suitable beamsplitter and, thus, have identical frequency. When tuned to line-center of the absorbing sample, the transmission of the probe increases owing to saturation by the strong pump beam interacting with the same subgroup of the inhomogeneously broadened medium (Figure 3).

The elimination of the first-order Doppler effect, in gaseous media, using this technique results in very high-resolution spectra. The residual linewidth is determined by homogeneous processes such as lifetime broadening, collisional (or pressure) broadening and power (or saturation) broadening. The latter effect is inevitable, as saturation is necessary, but may be controlled so as to contribute very little to the overall broadening. Power broadening becomes significant only when the laser intensity is appreciably in excess of the saturation intensity. Another limiting effect is transit time broadening: moving atoms spend only a limited time interacting with the narrow beams as they pass through. The consequent limit on the interaction time leads to conjugate broadening of the frequency of the transition as a result of the uncertainty principle.

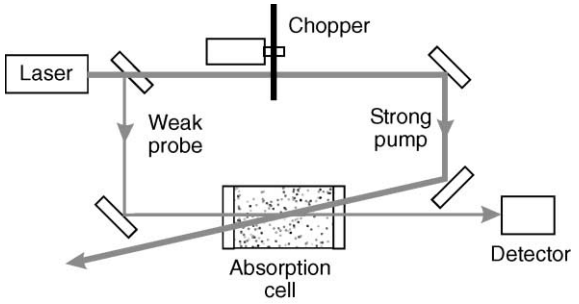

Figure 3 Schematic diagram of saturated absorption spectroscopy experiment. The saturating pump beam is chopped or modulated and the signal is processed using phase-sensitive detection to improve the signal-to-noise ratio.

The general problem of the spectral lineshape of signals in saturation spectroscopy is complex. Apart from the effects mentioned above, the lineshape will be affected by relativistic effects (second-order Doppler shifts), velocity-changing collisions, recoil effects from photon absorption and emission, velocity-dependent transit time broadening, optical pumping and laser lineshape effects.

Saturation spectroscopy is widely used in high-resolution spectroscopy for measurement of atomic and molecular transition frequencies, time and frequency standards using stabilized lasers, measurement of fundamental constants such as the Rydberg constant and the fine structure constant. Dynamical effects such as atomic collisions are also studied using saturation, whereby the relaxation of hole burning is measured in the time or frequency domain.

Polarization Spectroscopy

An important variation of saturation spectroscopy uses the change induced by a saturating beam in the real part of the complex refractive index, i.e., dispersion rather than absorption. Specifically, the technique of polarization spectroscopy employs a saturating beam that is circularly polarized to effect optical pumping on the degenerate lower level of a transition. The degenerate states may be identified, for example, with magnetic substates based on orientation of the intrinsic atomic or molecular angular momentum and labeled by the quantum numbers m_J. In equilibrium, the populations of all these degenerate substates will be equal and the optical properties of the system will then be isotropic. In particular, the polarization state of a linearly polarized probe beam will be unaffected by passage

through the medium. This probe is totally rejected by an analyzer (a linear polarizer set to transmit only light in an orthogonal plane). The linear polarized beam is a linear combination of two oppositely circular polarization states, σ^+ and σ^-, and both components experience the same complex refractive index. In the presence of a circularly polarized saturating pump beam, the distribution of population amongst the degenerate substates is disturbed from its equilibrium by optical pumping. The result will be an excess of population in higher or lower m_J states (a condition known as orientation) and this leads to optical anisotropy in the medium. The refractive index for σ^+ light is now different from that for σ^- light and a relative phase shift is introduced between these components of the linearly polarized probe resulting in elliptical polarization. A component of this elliptically polarized light will then be transmitted by the analyzer and is detected. When the strong pump beam is closely counter-propagating to the probe, then both beams interact with the same velocity subgroup as in Doppler-free saturation spectroscopy. The inhomogeneous (Doppler) broadening is thus significantly reduced. The technique provides a signal above an essentially 'zero' background and is thus capable of a higher signal-to-noise ratio than saturated absorption spectroscopy. How close to 'zero' the background is depends crucially on the degree of extinction by the analyzer. High-quality polarizer/analyzer devices can achieve extinction ratios of $1{:}10^{-8}$. Stress-induced birefringence in the windows of the cell containing the sample is a common limiting factor (Figure 4).

A probe laser of intensity I_{probe} is transmitted through a sample of length l with an intensity $I_{\text{PS}}(\omega)$ given by the following expression, that takes account of different contributions to the detected signal:

$$I_{\text{PS}}(\omega) = I_{\text{probe}}\left[\xi + \varphi^2 + b^2 + \frac{1}{2}\frac{b\Delta\alpha_{\pm}l}{(1+x^2)} + \frac{1}{2}\varphi\Delta\alpha_{\pm}l\frac{x}{(1+x^2)} + \left(\frac{1}{4}\Delta\alpha_{\pm}l\right)^2\frac{1}{(1+x)^2}\right] \quad [9]$$

where $x = 2(\omega_0 - \omega)/\gamma$ is the detuning from the resonance frequency ω_0 normalized by the halfwidth γ of the collision broadened line. The frequency-dependent terms provide absorptive (Lorentzian) and dispersive contributions to the total lineshape. The first three, frequency independent, terms in eqn [9] are responsible for a constant background signal. They originate from residual transmission of the polarizers (ξ), their accidental uncrossing (φ), and a possible residual birefringence (b) from optical elements between both polarizers in the probe beam path. ($\xi + b^2$), normally is in the range 10^{-6}. The differential absorption coefficient for left and right circularly polarized light, $\Delta\alpha_{\pm}$, at resonance ($x = 0$), is given by:

$$\Delta\alpha_{\pm}(x=0) = \Delta\alpha_{\pm}^0 = \alpha^+ - \alpha^- = \alpha_0 S_0 \Delta C_{JJ_1} \quad [10]$$

where α_0 is the unsaturated absorption coefficient, S_0 is the saturation parameter for the pump wave ($I_{\text{pump}}/I_{\text{sat}}$), and ΔC_{JJ_1} are Clebsch–Gordan coefficients for the respective transition and coupling case.

The dispersion-shaped component may be made to dominate by deliberately uncrossing the polarizer/analyzer combination to a small extent. This technique enhances the resolution of the transition frequency. Linewidths are limited by residual Doppler broadening owing to finite crossing angles of pump and probe beams, collisional broadening, transit time broadening, etc.

Applications of the technique have included Doppler-free spectroscopy of atomic transitions for precision measurements of fundamental constants, molecular spectroscopy and detection of atomic, molecular, and radical species in flames. By employing a different laser to accomplish the induced optical anisotropy from that used to probe the medium, molecular spectra can be simplified by the technique of 'polarization labeling'. Signals are obtained only when the probe and pump excite transitions sharing a common level and the particular transitions observed are sensitive to the selection rules for ΔJ, governing both pump and probe transitions. In this way P- and R-branch transitions can be distinguished.

Advantages of polarization spectroscopy include high sensitivity (10^2–10^3 times that of saturation spectroscopy), high signal-to-noise, simplification of

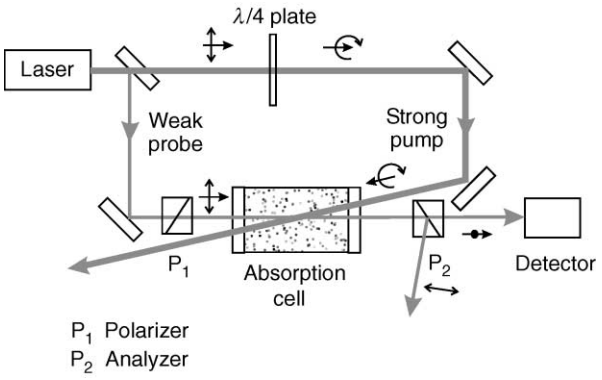

Figure 4 Schematic diagram of polarization spectroscopy experiment. Circularly polarized pump beam may be modulated for phase-sensitive detection of transmitted probe beam.

molecular spectra by polarization labeling, dispersion profiles for enhanced resolution, and for frequency stabilization techniques.

Multiphoton Absorption Spectroscopy

Multiphoton absorption is the term used to describe a process in which an atom or molecule makes a single transition between two of its allowed energy levels by absorbing the energy from more than a single photon. Sequential transitions, by which successive photons are absorbed via single-photon transitions between stationary energy levels, take place provided photons arrive within the lifetime of the intermediate state. Multiphoton transitions take place via 'virtual' energy levels. The lifetime of a virtual level is determined by the uncertainty principle to be the inverse frequency detuning from the nearest stationary energy level. Thus a high photon flux is usually required for multiphoton effects to be observed (Figure 5).

The simplest multiphoton effect, two-photon absorption, may be observed using strong atomic or molecular electronic transitions, even with modest laser power. The absorption is detected by observing the fluorescence from the spontaneous, radiative decay of the excited state. Two-photon absorption spectroscopy may be made Doppler-free by arranging absorption of one photon from each of two counter-propagating beams. The moving atoms experience opposite Doppler shifts $\mathbf{k}\cdot\mathbf{v}$ from each beam. The transition energy is thus:

$$E = (\hbar\omega + \mathbf{k}\cdot\mathbf{v}) + (\hbar\omega - \mathbf{k}\cdot\mathbf{v}) = 2\hbar\omega \qquad [11]$$

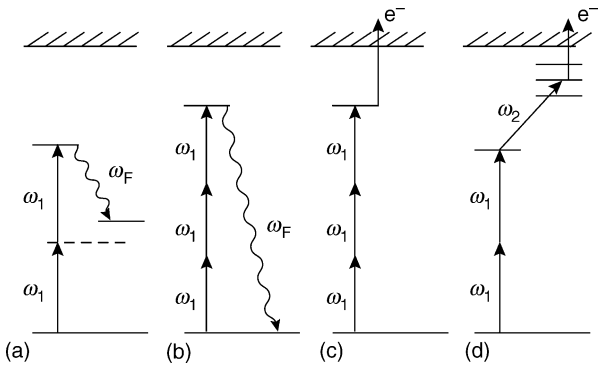

Figure 5 Multiphoton absorption spectroscopy. (a) Two-photon absorption using fluorescence detection of radiative decay at ω_F. (b)Three-photon absorption spectroscopy using fluorescence detection of radiative decay at ω_F. (c) Three-photon absorption spectroscopy using ionization detection following photoionization, collisional or field ionization. (d) Two-photon resonant multiphoton ionization spectroscopy; laser at frequency ω_1 is fixed and laser at ω_2 is tuned over transitions to high-lying levels.

Absorption of two photons from a single beam is prevented by choosing a transition between levels of the same parity and angular momentum quantum number, i.e., $\Delta J = 0$ and using circularly polarized light. Absorption of two σ^+ or σ^- photons gives $\Delta J = \pm 2$, which would be forbidden, e.g., on a n^2S–n'^2S transition in an alkali metal. This method of Doppler-free spectroscopy has the advantage that it involves all the atoms and not just the zero-velocity subgroup, as in saturation or polarization spectroscopy. In principle, it is also possible to use three-photon absorption, with the momentum of the wavevectors arranged to sum to zero, to achieve Doppler-free absorption on a transition between opposite parity states.

Instead of observing fluorescence following multiphoton absorption, the excited atom or molecule may be ionized by atomic collisions or by applying a d.c. electric field. Excitation of Rydberg levels (i.e., having high value of the principal quantum number n) by two- or three-photon absorption is readily accomplished. The sensitivity of this technique is enhanced by using two lasers. One laser at frequency ω_1 is tuned to a two-photon transition (energy $= 2\hbar\omega_1$) and the second laser ω_2 is tunable to excite transitions from the two-photon intermediate state to higher-lying levels (energy $= 2\hbar\omega_1 + \hbar\omega_2$). Thus, energy levels normally requiring excitation in the vacuum UV may be reached using visible frequency lasers. In such cases ionization detection may be more efficient than fluorescence since the nonradiative decay rate of these highly excited levels may exceed the fluorescence decay rate. The ion signal produced may be significantly amplified by the process of space charge amplification. A weak discharge established in the atomic vapor creates a space charge around the cathode. A single ion moving slowly through the space charge cloud acts to cancel the local field allowing many (up to 10^6) electrons to escape to the anode with a resulting amplification of 10^6 in the 'photoionization current'.

Multiphoton ionization spectroscopy is a sensitive method of recording highly excited energy levels. The sensitivity is enhanced in the technique of resonance ionization spectroscopy (RIS): two lasers are used such that the frequency of one laser is fixed close to a two-photon allowed transition and the second is tuned to excite a range of higher excited states. Absorption of an even number of photons allows excitation of levels having the same parity as the ground state and thus not accessible to normal absorption spectroscopy. In combination with a mass spectrometer to detect the ions produced by the multiphoton absorption resonance ionization mass spectrometry (RIMS), affords additional species

selectivity and sensitivity. RIMS finds application in high-resolution spectroscopy of rare isotopic species and is the basis for a scheme for isotope separation.

Coherent Third-Order Processes

An important class of spectroscopic techniques exploits the coherent interaction of three input waves via the nonlinear response of the medium. Specifically, the third-order term has the form:

$$\mathbf{P}_i^{(3)}(\omega_4, \vec{r}) = \chi_{ijkl}^{(3)}(\omega_1, \omega_2, \omega_3, \omega_4)\mathbf{E}_j(\omega_1, \vec{r}) \times \mathbf{E}_k(\omega_2, \vec{r})\mathbf{E}_l(\omega_3, \vec{r}) \quad [12]$$

where $\mathbf{E}_m(\omega_n)$ are complex field amplitudes and the subscript $m = i, j, k, l$ refers to each of the Cartesian coordinates x, y, z of the electric vector. $\chi_{ijkl}^{(3)}$ is a fourth-rank tensor. In condensed phase media, the third-order nonlinearity is readily observed, even with modest laser intensities. In the gas phase, although $\chi_{ijkl}^{(3)}(\omega)$ is small relative to $\chi^{(1)}$, its effect is enhanced when the incident fields are resonant and this nonlinear response may be used for spectroscopy. Equation [12] shows that the induced polarization couples three waves to radiate a fourth and describes a class of interactions known collectively as four-wave mixing.

The physics of four-wave mixing interactions may be visualized as the formation and read-out of a volume hologram. The three input beams are denoted as two pumps and one probe. The process involves the interference of one pump with the probe to form a spatially periodic grating pattern in the electric field distribution. The nonlinear response of the medium via $\chi^{(3)}$ leads to a spatial modulation of the refractive index – a laser-induced grating. The second pump beam generates a signal by scattering off this grating in a manner analogous to Bragg scattering of X-rays from regular crystal planes. The condition for generating a coherent scattered beam is equivalent to matching the momentum (or wavevectors) of the interacting photons, i.e., phase matching.

Degenerate Four-Wave Mixing (DFWM) Spectroscopy

The simplest case of four-wave mixing spectroscopy involves pump and probe beams of identical (i.e., degenerate) frequency to generate a signal at the same frequency. Spectra are generated as the frequency is tuned through atomic or molecular resonances where the interaction is strongly enhanced. In this degenerate case, the pump and probe interference pattern is stationary and the remaining pump beam scatters off this grating with the same frequency. As with all parametric processes, the interaction is phase matched by a suitable geometrical arrangement of the beams. A probe intersecting with counter-propagating pump beams leads to a signal that counter-propagates with the probe. This arrangement provides 'Doppler-free' lineshapes, since only those atoms with essentially zero velocity along the line of intersection of the beams contribute to the signal. Alternatively, pump and probe beams may be arranged to cross at an angle (usually small) in the forward direction – the 'forward geometry', with the resulting signal propagating at the same small angle to the incoming beams. Signals in this case are stronger, since all velocity classes may contribute but the lineshape is Doppler broadened (Figure 6).

An additional feature of the counter-propagating pump geometry is that the phase-matched signal arises from terms that involve products of fields with the complex conjugate of the incident

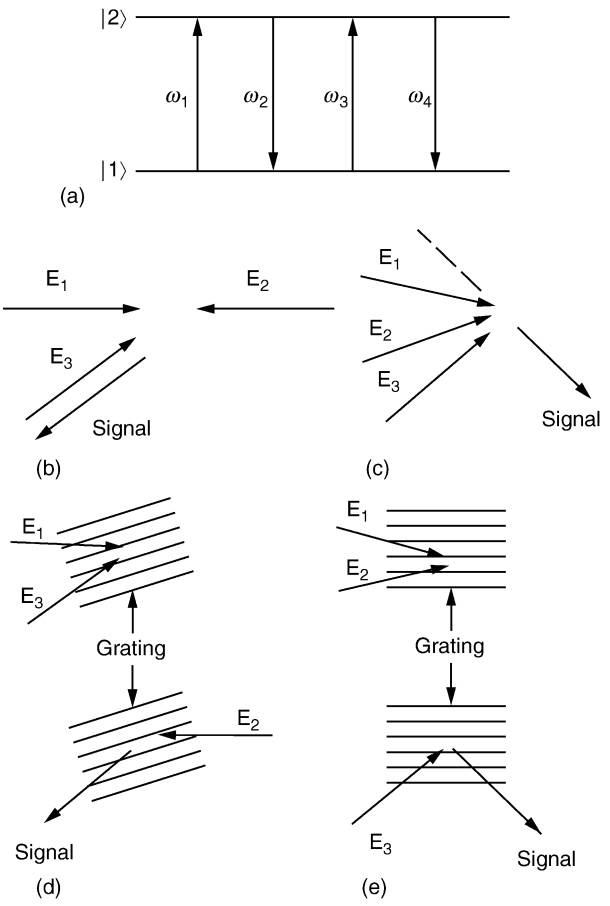

Figure 6 Degenerate four-wave mixing: (a) all input frequencies are degenerate, $\omega_1 = \omega_2 = \omega_3$ and give signal at the same frequency, ω_4. Phase matching geometries are shown in (b) counter-propagating pump (phase conjugate) and (c) forward geometry. (d) and (e) show the grating formation and read-out respectively.

probe field. The induced polarization radiating the signal wave has a component given by:

$$\mathbf{P}^{(3)}_{\text{signal}}(\omega) = \chi^{(3)}(\omega)\mathbf{E}_{\text{pump}}(\omega)\mathbf{E}_{\text{pump}}(\omega)\mathbf{E}^{*}_{\text{probe}}(\omega) \quad [13]$$

The backward propagating signal appears as a phase conjugated reflection of the incident probe wave. A probe wave that has propagated through a phase-distorting medium thus generates a signal with an initial phase distortion that will be undone as it retraces the path through the distorting medium. This phase conjugating property finds application in adaptive optics but also lends an advantage when DFWM is used as a spectroscopic probe in hostile or distorting environments, such as flames or plasmas. The counter-propagating pump geometry is often referred to as the phase conjugating geometry.

The intensity of the DFWM signal beam may be calculated using perturbation theory to derive $\chi^{(3)}(\omega)$ arising from saturated absorption. In the perturbation approximation, the probe beam is assumed to be weak and interacts with stationary atoms in the presence of counter-propagating, saturating pump fields. The signal is found from the phase-matched terms in the wave radiated from the induced polarization. When integrated over the atomic resonance line, the signal intensity, $I^{\text{int}}_{\text{sig}}$, is given by analytic expressions in the two limiting regimes of weak and strong saturation by the pump:

$$I^{\text{int}}_{\text{sig}} = \frac{|\mu_{12}|^8 N^2 k^2 T_1^2 T_2^3}{[1 + 4I_{\text{pump}}/I_{\text{sat}}(0)]^{5/2}} I^2_{\text{pump}} I_{\text{probe}} \quad [14]$$

when $I_{\text{pump}} \ll I_{\text{sat}}(0)$ and

$$I^{\text{int}}_{\text{sig}} \propto |\mu_{12}|^3 N^2 k^2 T_1^{-1/2} T_2^{1/2} I^{-1/2}_{\text{pump}} I_{\text{probe}} \quad [15]$$

when $I_{\text{pump}} \gg I_{\text{sat}}(0)$.

In these relations μ_{12} is the atomic dipole moment, N the atomic number density, $I_S(0) = \hbar^2/T_1 T_2 |\mu_{12}|^2$ is the line-center saturation intensity, and T_1 and T_2 are the longitudinal and transverse relaxation times, respectively. Extensions of the basic theory accommodate the effects of moving absorbers (Doppler effect) in both the phase-conjugate and forward phase matching geometry.

These results are derived using perturbation theory, by assuming that the probe field is weak. In practice the signal is optimized when pump and probe are of equal intensity and approximately equal to the saturation intensity. This situation violates the perturbation theory assumption but the signal intensity may be derived using nonperturbative analytical methods, although the resulting expression is more complicated. Alternatively, the quantum mechanical equations for the nonlinear susceptibility can be solved numerically to find the signal level for arbitrary intensity of the incident fields. Optimum signal-to-noise ratio in the spectra is achieved using approximately saturating intensities.

The sensitivity of resonant DFWM and the coherent nature of the signal beam suits the process to spectroscopy of nonfluorescing or trace molecular species, such as radicals created in chemical reactions. Equation [15] shows that the DFWM signal becomes relatively insensitive to collisional effects when the incident lasers saturate the transition. This feature of DFWM gives it an additional advantage over laser-induced fluorescence in optical diagnostic applications where quantitative evaluation of fluorescence intensity is hampered by collisional quenching. The state and species selectivity afforded by resonant DFWM is exploited in diagnostics of combustion and plasma processes, where the reduction of Doppler broadening allows high-resolution spectra from high-temperature gases. The relative intensity of spectral lines is used to derive temperature and concentration information with time and space resolution.

Additional selectivity is provided by using two input frequencies in two-color four-wave mixing (TC-FWM), to probe molecular excited state dynamics. The TC-FWM process uses resonant enhancement on two coupled transitions, i.e., the pump beams excite one transition and the probe and signal are generated on another transition having a common level with that excited by the pumps.

Coherent Raman Spectroscopy

The classical theory of spontaneous Raman scattering shows that a nonresonant pump of frequency ω_p wave can excite a resonance ω_m in a molecule with a nonlinear polarizability $\beta(x)$. (x is the spatial coordinate of the internuclear potential.) The wave resulting from this inelastic scattering is a Stokes wave of frequency $\omega_S = \omega_p - \omega_m$. The propagation of the Stokes wave is governed by the complex Raman susceptibility (**Figure 7a**):

$$\chi_{\text{Raman}}(\omega_s) = \chi'_{\text{Raman}}(\omega_s) + i\chi''_{\text{Raman}}(\omega_s) \quad [16]$$

This generated Stokes wave may then couple with the pump to drive the molecular resonance coherently leading to amplification of the Stokes wave at the expense of the pump. This process of stimulated Raman scattering (SRS), provides gain if the amplification exceeds the loss due to absorption, scattering, etc. There is, therefore, a definite threshold intensity that the pump must satisfy to observe SRS. The SRS

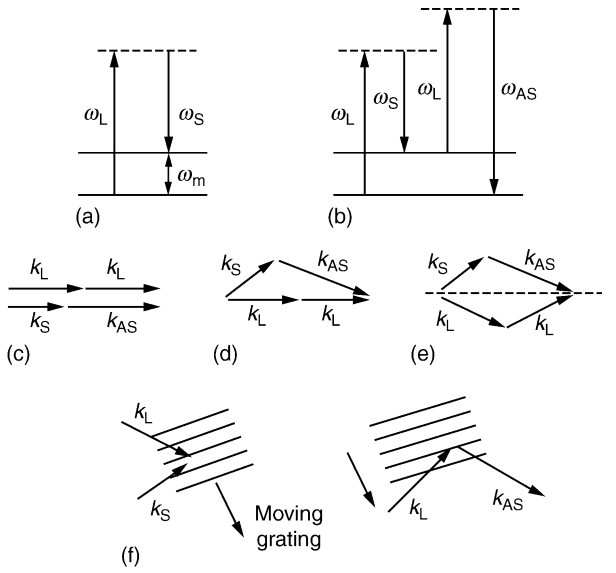

Figure 7 Coherent Raman spectroscopy. (a) Spontaneous Raman scattering of input pump ω_L producing Stokes wave ω_S in inelastic scattering. (b) Coherent anti-Stokes Raman scattering (CARS). Phase matching geometries for CARS is shown for a nondispersive medium in (c) and dispersive media in (d) and (e). The planar boxcars geometry in (e) may be folded along the dotted line (folded boxcars geometry) to separate the signal into an orthogonal plane from the pump beams to reduce scattered pump light reaching the detector.

gain $g(\omega_s)$ at the Stokes frequency ω_s is given by:

$$g(\omega_s) = -\frac{k_s}{2n_s^2}|E(\omega_L)|^2\chi''_{\text{Raman}}(\omega_s) \qquad [17]$$

where k_s and n_s are the wavevector and refractive index for the Stokes wave, $E(\omega_L)$ is the field amplitude at the pump laser frequency ω_L, and $\chi''_{\text{Raman}}(\omega_s)$ is the imaginary part of the complex Raman susceptibility:

$$\chi''_{\text{Raman}}(\omega_s) = \frac{-\varepsilon_0 N\left(\dfrac{\partial\beta}{\partial x}\right)^2\gamma}{32m_e\omega_v\left\{(\omega_m-(\omega_L-\omega_S))^2+\dfrac{\gamma^2}{4}\right\}} \qquad [18]$$

In this expression $\partial\beta/\partial x$ is the variation of polarizability β with internuclear displacement x, N is the molecular population density, and γ is the linewidth due to damping. Spectroscopy based on SRS provides signals that are many orders of magnitude stronger than those from spontaneous Raman scattering, and is widely used to study spectra of complex molecules having no absorption spectra in the visible region.

A four-wave mixing interaction, involving a pump and probe beam of different frequencies, generates a nonstationary grating. The signal generated by scattering of a second pump beam off this moving grating is Doppler-shifted to lower or higher frequency. These signal beams correspond respectively to Stokes or anti-Stokes waves in Raman scattering. A probe beam at the Stokes frequency will thus interact with a pump beam to generate a coherent signal at the anti-Stokes frequency; a process known as coherent anti-Stokes Raman scattering (**Figure 7b**). A probe at the anti-Stokes frequency correspondingly gives the process of coherent Stokes Raman scattering (CSRS). Phase matching is necessary for both CARS and CSRS and is satisfied by an appropriate arrangement of the incident wavevectors (**Figure 7c,d** and **e**).

CARS has proven to be a valuable spectroscopic technique in a wide variety of applications. A CARS spectrum is generated by scanning the frequency of the probe, i.e., the Stokes laser. The signal strength is given by

$$I_4 = I_{\text{CARS}} = \frac{\omega_4^2}{n_1^2n_2n_4c^4\varepsilon_0^2}I_1^2I_2|\chi_{\text{CARS}}|^2l^2 \times\left(\frac{\sin(\Delta kl/2)}{\Delta kl/2}\right)^2 \qquad [19]$$

where I_1 and I_2 are the intensity of the pump and Stokes beams, respectively, l is the interaction length, and n_i are the refractive indices at frequency ω_i. The maximum signal is generated when the phase mismatch $\Delta k = 0$. The third-order susceptibility, $\chi^{(3)} = \chi_{\text{CARS}}$, in general consists of a nonresonant part $\chi^{(3)}_{\text{nr}}$, which is independent of the frequency of the exciting beams, and a Raman-resonant contribution $\chi^{(3)}_{\text{r}}$:

$$\chi^{(3)} = \chi^{(3)}_{\text{nr}} + \chi^{(3)}_{\text{r}} \qquad [20]$$

The lineshape in coherent Raman spectroscopy is affected by interference between resonant and nonresonant contributions. This effect is exploited to derive the concentration of the resonant (Raman active) species relative to that of the background of known density. A more common application of CARS, however, is for temperature measurement. The dependence of the signal intensity on $|\chi_{\text{CARS}}|^2$, and therefore on the square of the molecular population of the initial state, yields a spectrum from which the temperature may be derived by assuming a Maxwell–Boltzmann distribution over the state populations.

A particularly useful application of CARS employs a narrow linewidth pump laser and a

broad bandwidth Stokes laser. CARS signals are generated simultaneously on all frequencies such that the corresponding Stokes frequency is available from the broadband probe. The spectrum recorded with a single laser pulse can thus provide population information on a wide range of molecular states, giving time- and space-resolved measurement of temperature and concentration.

CARS and CSRS spectroscopy is applied to both gas and condensed phase media. Owing to the higher density in the latter, signals may be strong in spite of the two-photon nature of the resonant interaction.

Time Domain Four-Wave Mixing Spectroscopy

Four-wave mixing spectroscopy may also be executed in the time domain. The three incident waves may arrive as pulses separated in time by variable delays. The interaction is, therefore, mediated by the atom or molecule's induced polarization or coherence. DFWM, CARS, and CSRS processes may thus be used to study ultrafast relaxation since the signal intensity gives a measure of the coherence decay in the intervening delay between the pulses. These processes are intimately related to coherent transient spectroscopy using measurements of free induction decay, photon echoes, and stimulated photon echoes.

Laser-Induced Grating Spectroscopy

The four-wave mixing processes discussed above involve a spatial modulation of the molecular population and a consequent modulation of the refractive index for resonantly interacting waves. The signals are radiated by the coherent oscillations of the molecular populations that decay rapidly. Relaxation processes result in transfer of energy from the excited molecular states, leading to a temperature and density grating in the bulk medium with a period Λ, given by:

$$\Lambda = \lambda_{\text{pump}}/(2 \sin \theta_1) \qquad [21]$$

where θ_1 is the angle between the interfering beams of wavelength λ_{pump}. A nonresonant wave of wavelength λ_{probe} may be scattered by this laser-induced grating provided it is incident on the grating at the angle θ_2 satisfying the Bragg condition:

$$\theta_2 = \sin^{-1}(\lambda_{\text{probe}}/2\Lambda) \qquad [22]$$

The periodic temperature/density grating, when induced by a short duration laser pulse, is accompanied by two oppositely propagating acoustic waves. The reflectivity of Bragg scattering is temporally modulated as the acoustic waves traverse the stationary grating at the local sound speed. Measurement of the period of these oscillations yields the sound speed from which the temperature may be derived. The stationary grating and acoustic waves decay by diffusive and damping processes, dependent upon the bulk medium properties. Measurement of the decay time of the grating induced in gas phase media yields the gas pressure if the gas dynamic parameters are known (Figure 8).

Laser-induced grating spectroscopy (LIGS), has been widely employed for studies of condensed phase relaxation processes. Applications have also been developed for gas phase studies using resonant absorption to enhance the thermal grating component. A grating may, however, also be induced in response to the electrostrictive effect of the high electric field in the interference pattern of two intense pump waves. Such electrostrictive gratings do not require resonant absorption and their spectroscopic utility centers on the study of relaxation effects in the molecular medium.

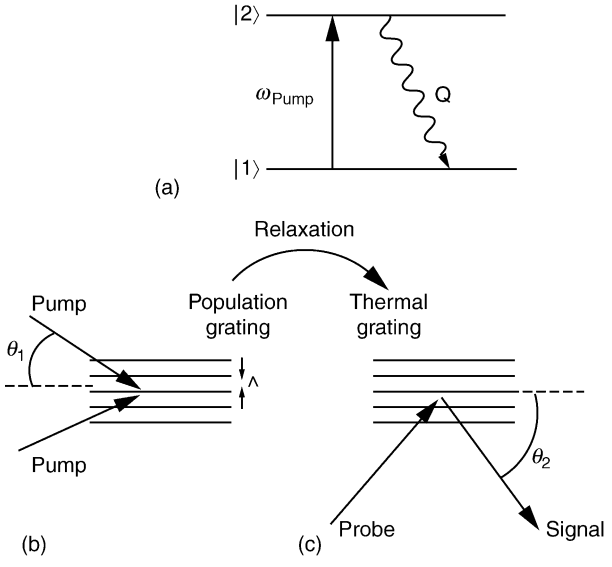

Figure 8 Laser-induced thermal grating spectroscopy. (a) Absorption of energy from pump lasers creates excited molecular population in grating pattern shown in (b). Spacing of laser induced grating Λ is set by angle of intersection of pumps. Quenching, Q, of excited population by collisions transfers heat to bulk medium and forms thermal grating. (c) Probe incident at Bragg angle θ_2 is scattered to form signal.

List of Units and Nomenclature

Formulae are expressed in SI units

c	Speed of electromagnetic wave *in vacuo*
$\mathbf{E}$	Electric field amplitude
$g_0(\omega)$, $g(\omega)$	Gain coefficient at line center, at frequency ω
h	Planck's constant
I	Intensity of electromagnetic wave
I_{sat}	Saturation intensity of medium
$\mathbf{k}$, k	Wave vector, scalar value of wave vector ω/c
m_e	Mass of electron
n_m	Refractive index of medium for mth beam
N	Atomic or molecular population density
$\mathbf{P}$	Polarization field amplitude
T_1	Longitudinal relaxation time
T_2	Transverse relaxation time
α_0, $\alpha(\omega)$	Absorption coefficient at line center, at frequency ω
$\beta(x)$	Molecular polarizability as function of internuclear separation x
ε_0	Permittivity of free space
μ_{12}	Dipole moment for transition between energy levels 1 and 2
ν	Frequency of electromagnetic wave
$\chi^{(n)}$	nth order susceptibility
ω	Angular frequency of electromagnetic wave

Introduction

Inelastic light scattering, the optical analogue of Compton scattering, had been predicted to occur by Smekal in 1923, but it was Chandresekar Venkataraman Raman who provided the first experimental demonstration of the phenomenon in February 1928. Only a few months later in 1928 the Russian scientists, Landsberg and Mandelstam observed inelastic light scattering from a quartz crystal. In spite of initial claims to the contrary, this was the same effect that had been observed by Raman, although the Russian scientists did not acknowledge this, preferring to call the effect 'combinatorial scattering'. It was not until the 1970s that the effect became known as Raman scattering everywhere, including Russia.

As typically practised, Raman spectroscopy involves laser excitation of a sample and measurement of the wavelength and intensity distribution of the scattered Raman light. When a microscope is used for delivering laser excitation and/or collecting the inelastically scattered light, the technique is referred to as Raman microscopy. However, it is important to

recognize that, apart from the differences in sampling configuration, there are no fundamental differences between Raman microscopy and Raman spectroscopy; the terms merely identify the different sampling techniques.

Since its invention in 1960, major advances in the technology of the laser have occurred, resulting in the wide variety of laser light sources that are currently available for Raman spectroscopy. Characteristic properties of laser systems for Raman microscopy will be described in this chapter, following an introduction to the technique and its applications in the next section below. Then, the commonly used laser sources for Raman microscopy are categorized according to the wavelength regions of their emissions, along with their merits and drawbacks for each application. The chapter will consider mainly continuous wave laser sources, because pulsed laser beams that are tightly focused with microscope optics give very high irradiance that would destroy most samples.

Raman Microscopy

The first experimental Raman microscopes were developed in the mid-1970s by two independent groups, and it was not long before the first generation of Raman microscopes were subsequently commercialized. Many of these early instruments simply consisted of commercial optical microscopes coupled to Raman spectrometers, as shown in Figure 1. It was recognized that the use of a microscope for sampling in this way can facilitate the Raman examination of tiny particles of micrometer dimensions.

The optical lay-out in Figure 1 shows an infinity corrected microscope. The advantage of using this, rather than a standard tube length microscope, is that its length can be extended in order to incorporate additional optical elements that are required for coupling to the Raman excitation and collection optics. In the optical layout, the incident laser beam is spatially filtered by a pinhole, D_1, in order to remove the diffraction rings and give a point source. The laser light is then partially reflected by beamsplitter, B_1, and focused on to the sample by the microscope objective. The back-scattered Raman radiation is collected by the same microscope objective, partially transmitted by the beamsplitter, and directed into the entrance slit of the Raman spectrometer by means of coupling optics. The accurate location of an aperture, D_2, at the focal point improves the spatial resolution and allows depth profiling of transparent samples. The two pinholes, D_1 and D_2, act as spatial filters and are referred to as confocal diaphragms. The Raman microscope is described as being confocal, because out-of-focus light, collected from outside the focal volume, is rejected.

The use of the beamsplitter, in the optical path of early Raman microscope designs, gives rise to significant losses of the precious Raman

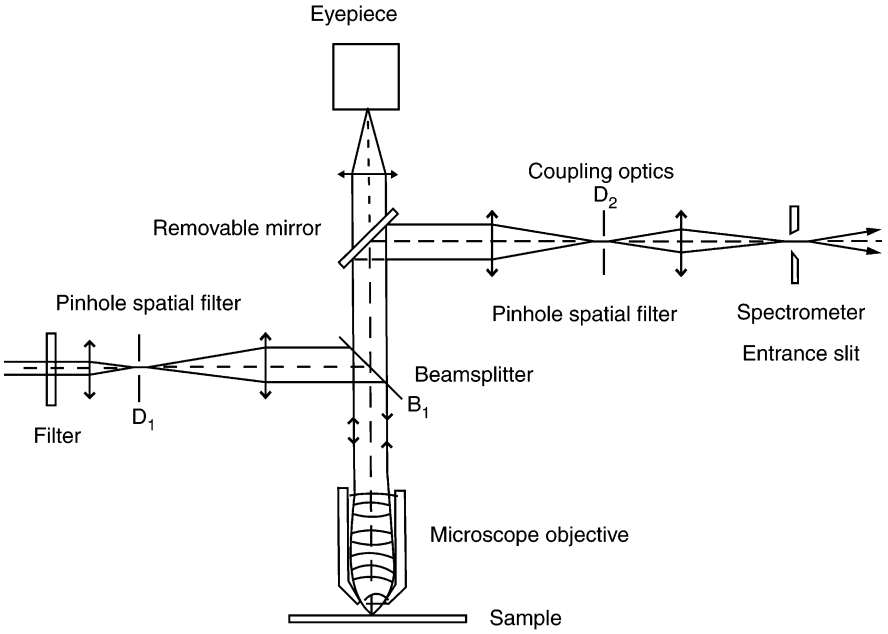

Figure 1 Diagram of the optical layout of a visible Raman microscope (Reproduced from Turrell G, Delhaye M and Dhamelincourt P (1996) Characteristics of Raman microscopy. In: Turrell G and Corset J (eds) *Raman Microscopy. Development and Applications*, 2. London: Academic Press).

scattered light. If a 50:50 beamsplitter is used then half of the incoming laser light is lost by transmission at B_1 and, more significantly, half of the Raman scattered light is lost by reflection at B_1. As long as a higher laser power can be employed, it is better to use a 90:10 beamsplitter that transmits 90% of the light and reflects 10%; then, only 10% of the incoming laser light is directed by B_1 on to the sample, but 90% of the Raman scattered light is transmitted by B_1 towards the detector and only 10% of the Raman light is lost by reflection at B_1. The efficiency of a beamsplitter can be defined as the product of the reflectivity at the laser wavelength and the transmission at the Raman-shifted wavelength. Thus, conventional 50:50 and 90:10 beamsplitters would have efficiencies of 25% and 9%, respectively. Recently, however, holographic notch filters have been developed which can be used as higher efficiency beamsplitters. These typically have a laser rejection contrast ratio of better than 10^4, reflecting ca. 90% of the laser excitation and transmitting ca. 90% of the Raman scattered light, thus giving an efficiency of ca. 81%. Due to these considerations, higher throughput, commercial Raman microscope designs usually incorporate a holographic notch filter.

The importance of Raman microscopy stems from the fact that it is the only microanalytic method available today, by use of which it is possible to identify, or characterize, small particles of micrometer dimensions *in situ*. It is also advantageous that no sample preparation is required when performing Raman microscopy.

The fundamental limit of the lateral spatial resolution (i.e., for a diffraction limited focus) is the separation at which the maximum of one Airy disc function just touches the first minimum of an adjacent Airy disc, given by:

$$\text{Lateral spatial resolution} = \frac{1.22\lambda}{2\text{NA}} \qquad [1]$$

where λ is the wavelength of the light and NA is the numerical aperture of the microscope objective.

The axial Airy disc function determines the resolution in the longitudinal direction. A good estimate of the axial resolution limit for low numerical aperture is given by:

$$\text{Axial spatial resolution} = \frac{2\lambda}{(\text{NA})^2} \qquad [2]$$

When the sample is heterogeneous and exhibits fluorescence that is not evenly distributed within the sample, a region of the sample can be selected with the microscope that shows the minimum amount of fluorescence. If the fluorescence is intrinsic to the sample itself, then it is possible to use the shift subtract technique and/or temporal discrimination between the fluorescence and the Raman scattering. The latter can be achieved by Kerr gate fluorescence rejection, in which a pulse of light is used to close a Kerr gate shutter. The problem with this approach, however, is that it uses a laser pulse, and even pulses of modest energy will have extremely high irradiance when focused to a tiny spot by a microscope objective. Such laser pulses would inevitably destroy the sample under a microscope.

Another approach for reducing fluorescence is to use near infrared excitation, which is low enough in energy so that absorption cannot occur to promote electronic transitions. The technique of Fourier Transform Raman (FTR) spectroscopy often offers the best chance of obtaining Raman spectra from fluorescent samples for this reason. Low energy excitation of wavelength equal to 1064 nm, provided by a Nd:YAG laser, is normally used for FTR. Disadvantages are that the Raman scattering efficiency is low relative to that obtained with visible excitation, due to the ν^4 dependency (ν^4 refers to Rayleigh scattering of the Raman light). This is compensated to some extent by employing a high throughput (Jacquinot advantage) interferometer. However, this works better for macro rather than micro samples. This is because the coupling of a microscope to an FT Raman spectrometer has a fundamental drawback; the microscope is throughput limited, so the high throughput advantage of the FTR spectrometer cannot be realized in FTR microscopy. The image of the Jacquinot stop (the large circular aperture which is the entrance to the interferometer) at the sample plane typically has a diameter of a few hundred μm, which is much larger than particles with diameters of ca. 1 μm having similar dimensions to the waist diameter of the 1064 nm light excitation at its diffraction-limited focus. Consequently the throughput advantage of the interferometer is not fully exploited and there is a trade-off of spatial resolution with signal-to-noise at the detector. For this reason, the typical spatial resolution that is achieved is in the range of 15–100 μm rather than 4 μm, as claimed in the literature. Bruker has commercialized an FTR microscope by coupling an optical microscope to an FTR spectrometer with near infrared optical fibers.

An approach that offers more promise for reducing fluorescence and achieving spatial resolution close to the diffraction limit is to use near infrared excitation in conjunction with dispersive Raman microscopy. For example, semiconductor lasers operating from 785 to 852 nm can be used in conjunction with sensitive multichannel silicon-based CCD arrays. If longer excitation wavelengths are necessary, in order to

overcome the problems with fluorescence, then diode lasers can be used that emit at longer wavelengths in conjunction with dispersive Raman spectrometers equipped with multichannel near infrared (NIR) detectors, e.g., Ge- or InGaAs-array detectors.

The applications of Raman microscopy cover many areas, including material science, the earth sciences, environmental science, biology and medicine, forensic science, and even the analysis of artworks. These areas are too wide ranging to be described in detail here, but the interested reader is referred to the Further Reading section at the end of this article.

Characteristics of Laser Sources

The laser is an excellent light source for Raman spectroscopy to such an extent that the terms 'Raman spectroscopy' and 'laser Raman spectroscopy' are synonymous for all but the most esoteric experiments, for example, with synchotron sources. Indeed, the advent of the laser was the stimulation for the renaissance of Raman spectroscopy in the 1960s, given its special properties, such as monochromaticity, high intensity, beam collimation, and coherence.

The characteristics of laser light and the advantages it offers to Raman microscopy are now considered.

Beam Quality

The light inside a laser tube is formed from a number of standing waves having distinct vibrational modes. There are a limited number of these modes transverse to the beam and these are characterized by the TEM_{pq} number (where p and q can be 0, 1, 2,...) where TEM is an acronym for 'transverse electromagnetic'. When a laser is operating in its fundamental TEM_{00} mode, light rays are reflected on axes between the end mirrors of the laser cavity. The '00' indicates that there are no nodes in the beam profile (Figure 2a), and the laser beam has a Gaussian intensity profile in the radial direction:

$$I(r) = I_0 \exp\left(-\frac{2r^2}{w^2}\right) \qquad [3]$$

where $I(r)$ is the irradiance at a radial distance r from the axis of the beam, I_0 is the axial irradiance, and w is the beam radius.

For higher-order modes, a number of nodes are observed in the beam profile, which arise from off-axis light rays being reflected between the end mirrors, for example, the TEM_{11} mode has two nodes which are mutually perpendicular (Figure 2b).

The propagation characteristics of a Gaussian beam can be fully defined, either by the diameter of the beam waist or by the far-field divergence.

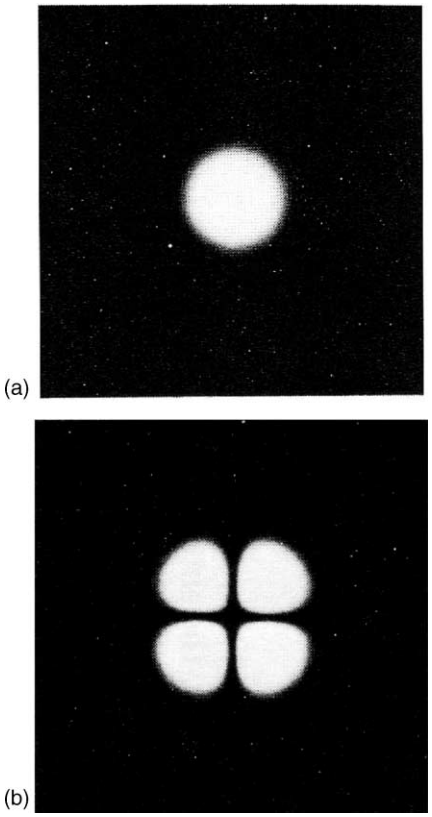

Figure 2 Transverse electromagnetic modes formed with confocal concave mirrors, (a) TEM_{00}, and (b) TEM_{11}. (Reproduced with permission from Young M (1977) *Optics and Lasers: an Engineering Approach.* Berlin, Heidelberg: Springer-Verlag

Consequently, it is only necessary to know the diameter of the beam waist ($2w_0$), or the diameter of the beam ($2w_z$) at a longitudinal distance z from the waist, in order to determine the propagation characteristics of the beam:

$$w(z) = w_0\sqrt{1 + \left(\frac{z}{z_R}\right)^2} \qquad [4]$$

$$R(z) = z\left[1 + \left(\frac{z_R}{z}\right)^2\right] \qquad [5]$$

where the quantity $z_R = \pi w_0^2/\lambda$ is known as the Rayleigh range of the beam, λ is the wavelength of the laser radiation, and $R(z)$ is the radius of curvature of the wavefront at a distance z from the beam waist.

The wavefront is planar at the minimum beam waist and the Rayleigh range is the distance from the beam waist to the location at which the wavefront is most curved (Figure 3), the region from the waist to

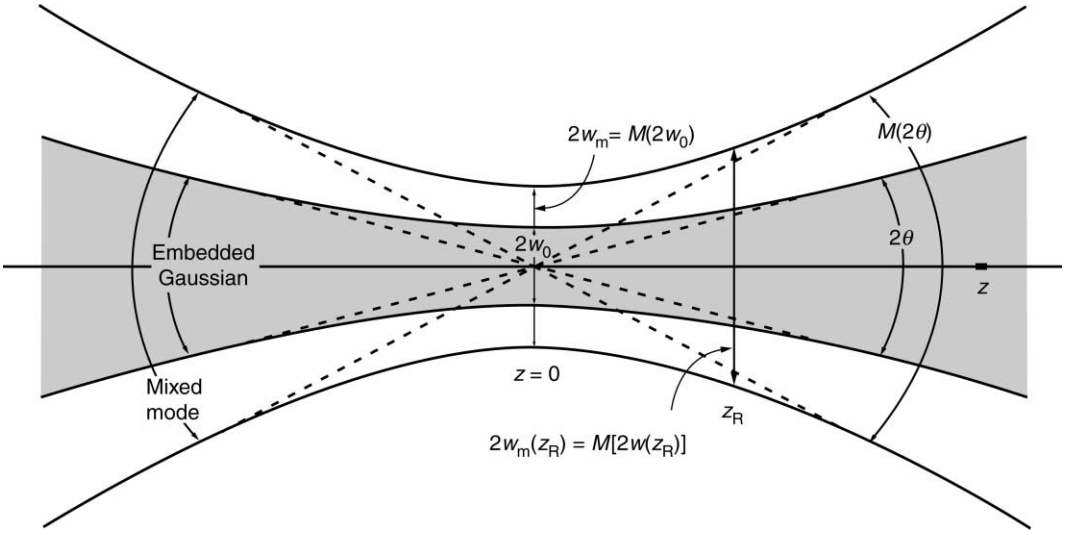

Figure 3 The Rayleigh range and embedded Gaussian (adapted from http://beammeasurement.mellesgriot.com/tut_m2.asp).

the Rayleigh range being the near field. Beyond approximately ten times the Rayleigh range, in the far field, the beam diverges as a cone with approximately straight sides. It can be seen by substituting $z = z_R$ into eqn [4] that the beam diameter at the Rayleigh range is $\sqrt{2}$ times the waist diameter.

Unfortunately laser beams do not conform to pure Gaussian functions and therefore they do not propagate according to the above equations. As a result, a dimensionless beam propagation parameter was devised in the early 1970s. This parameter, known as the M^2 factor or the 'times diffraction limit', is based on the brightness theorem, which states that for any laser beam the product of the beam diameter and the far-field divergence is a constant. Thus, M^2 is defined as the ratio of the laser beam's multimode diameter-divergence product to the ideal diffraction-limited (TEM_{00}) beam diameter-divergence product:

$$M^2 = \left(\frac{2w_m \, \Theta_m}{2w_0 \, \theta_0} \right) \qquad [6]$$

where Θ_m is the laser beam's multimode divergence, θ_0 is the theoretical diffraction-limited divergence, $2w_m$ is the laser beam's multimode waist diameter, and $2w_0$ is the ideal diffraction-limited beam waist diameter.

Alternatively, M^2 can be defined as the square of the ratio of the multimode beam diameter ($2w_m$) to the diffraction-limited beam diameter ($2w_0$):

$$M^2 = \left(\frac{2w_m}{2w_0} \right)^2 \qquad [7]$$

The intensity of the beam has a Gaussian distribution in the radial direction, but the accepted definition of beam diameter is the distance at which the intensity has fallen to $1/e^2$ (i.e., ca. 13.5%) of its axial intensity, as can be seen by setting $r = w$ in eqn [3] above. This definition only applies properly to Gaussian beams; for other beam profiles the diameter can be calculated using a second moment measurement of the entire beam.

The real beam, then, can be treated as Gaussian by substituting an artificial wavelength $M^2\lambda$ into the equations that apply to an ideal diffraction-limited TEM_{00} beam. The ideal TEM_{00} Gaussian can be superimposed as an 'embedded Gaussian' on the optical diagram of the real multimode beam (Figure 3). It can be seen that the multimode beam has a waist diameter and a divergence that are both M times larger than those of the embedded Gaussian.

The M^2 factor has a value of unity for an ideal diffraction-limited TEM_{00} beam, and values of greater than unity for all other beams; it can be as high as several hundred for a distorted beam of poor quality. This is an important parameter where a tightly focused laser spot (e.g., confocal Raman microscopy) or low divergence (e.g., remote sensing) are required.

Polarization

Although polarization is not an inherent property of laser light, lasers provide plane polarized light when the end windows of the laser tube are mounted at Brewster's angle (θ_B):

$$\theta_B = \tan^{-1} n \qquad [8]$$

where n is the refractive index of the window material for the appropriate wavelength of laser light. For this angle, reflected light is completely plane polarized and consequently the laser light that is generated is also plane polarized. Brewster windows are often used inside the laser cavity in order to reduce reflection losses. This is important in low-gain lasers such as HeNe lasers where laser action could be prevented by reflection losses. Air-cooled ionic gas lasers typically deliver highly linearly polarised output with ratios exceeding 1000:1.

The polarization property of the exciting light is used a great deal in Raman spectroscopy. In combination with the polarization properties of the Raman scattered light, it can be used to determine the depolarization ratios, ρ, of Raman bands in the solution state. In solid state studies it can be used to determine the degree of orientation, for example, in polymeric fibers or films, and in single crystal studies it can be used to determine the symmetry classes of the Raman active vibrations. In such studies a linear polarizer is used to improve the degree of plane polarization of the laser light, and a half-wave plate is used to rotate the plane of polarization by 90°.

Plane polarized laser light can be converted to circularly polarized laser light which is required for Raman optical activity (ROA) studies. For example, plane polarized 514.5 nm laser light provided by an argon ion laser can be converted to circularly polarized light by an electro-optic modulator. As CCD detectors are usually employed in present-day ROA experiments and they have relatively long sampling times, slow polarization modulation is required which can be achieved by periodically rotating a quarter-wave plate or by applying a square quarter-wave voltage to a Pockels cell.

Whereas optical isomers or enantiomers give identical Raman spectra, they are distinguished in the ROA experiment by the sign of the ROA signal. Indeed, the sign can be used to determine the absolute configuration of a chiral molecule. Also the enantiomeric excess of mixtures of enantiomers can be determined in such experiments, with obvious applications in the pharmaceutical industry, and the conformations of biological molecules, for example, proteins, nucleic acids, sugars, and viruses, can be determined.

Up until now, the ROA technique has been practised by no more than a handful of research groups world-wide, but it is expected that this situation will change in the near future, since the first commercial ROA spectrometer (the ChiralRAMAN spectrometer) has recently been launched by Biotools Inc. This spectrometer makes use of a solid state laser as the source of the polarized laser light.

Beam Divergence

Referring to Figure 3, the full divergence angle, Θ, for the fundamental TEM_{00} Gaussian beam is given by:

$$\Theta = \lim_{z \to \infty} \frac{2w(z)}{z} = \frac{2\lambda}{\pi w_0} \qquad [9]$$

From eqn [4] it can be seen that the spot size increases linearly with the longitudinal distance z and, from eqn [9], that it diverges at a constant cone angle, Θ. It can also be seen from eqn [9] that the smaller the spot size, w_0, the greater the beam divergence angle, Θ.

Indeed, a highly divergent beam is a problem with edge-emitting laser diodes due to the small dimensions of the light source. Furthermore, it is much smaller in the vertical direction than in the horizontal, giving rise to an elliptical output beam that diverges much more rapidly in the vertical direction than in the horizontal. The highly divergent, elliptical beam can be corrected, to an extent, with a cylindrical lens, but the inherent problem of a small, elliptical source can never be completely corrected.

In contrast, vertical-cavity surface-emitting semiconductor lasers (VCSELs) do not have the same limitations on beam divergence because the cavity is in the vertical direction and the light emission occurs from the surface, which has a much larger area than the light source of an edge emitter. Indeed, frequency-doubled green and blue semiconductor lasers are now available, having beams with M^2 values of less than 1.1 and beam divergences of a few milliradians. In terms of these beam characteristics, it appears that these lasers are beginning to challenge the argon ion laser.

Emission Linewidth

The laser linewidth limit, $\Delta\nu_L$, is given by the Schawlow–Townes expression:

$$\Delta\nu_L = \frac{2\pi h\nu(\Delta\nu_c)^2}{P_{out}} \qquad [10]$$

where $\Delta\nu_c$ is the linewidth of the passive resonator, $h\nu$ is the photon energy, and P_{out} is the laser power output.

The power output, P_{out}, is equal to the number of photons, N_p, in the resonator times the energy per photon, $h\nu$, divided by the photon lifetime, τ_c:

$$P_{out} = \frac{N_p h\nu}{\tau_c} \qquad [11]$$

Furthermore, the width $\Delta\nu$ of the resonance curve, at which the intensity has fallen off to half the maximum

value, is given by:

$$\Delta\nu_c = (2\pi\tau_c)^{-1} \quad [12]$$

Substituting for P_{out} and $\Delta\nu_c$ from eqns [8] and [9] into eqn [10] gives the limit for the linewidth, $\Delta\nu_L$:

$$\Delta\nu_L = \frac{\Delta\nu_c}{N_p} \quad [13]$$

The linewidth of a laser is characterized by its Q factor:

$$Q = \frac{\nu}{\Delta\nu} \quad [14]$$

where ν is the frequency of the laser line and $\Delta\nu$ is the linewidth.

Other useful relationships involving linewidth parameters are:

$$Q = \frac{\lambda}{\Delta\lambda} \quad [15]$$

and

$$\Delta\tilde{\nu} = -\frac{\Delta\lambda}{\lambda^2} \quad [16]$$

where λ and $\Delta\lambda$ are the wavelength and linewidth (in units of metres), respectively, and $\Delta\tilde{\nu}$ is the linewidth expressed as a wavenumber (in units of cm^{-1}).

The Q factor can be as high as 10^8 which is of great use in high resolution spectroscopy.

Visible Lasers

Helium-Neon Laser

The helium-neon laser is continuously pumped electrically using a high dc voltage of up to 1 kV. The gain medium consists of a gas mixture of about 10 parts helium to each part of neon at a pressure of about 3 Torr. The gain of this medium is extremely low, hence the requirement for Brewster-angle windows to eliminate reflection loss of the light polarized in the plane that includes the axis of the laser and the normal to the Brewster window. Due to this requirement, the light output is necessarily plane polarized.

The pumping excites helium atoms by electron impact, and resonant energy transfer to neon atoms then occurs via collisions of the gaseous atoms (Figure 4). This creates a population inversion in the neon atoms, enabling the laser transition to occur at 632.8 nm. Following emission, the neon atoms decay nonradiatively down to their metastable $2p^53s^1$ level from which they decay back down to the ground state via collisional de-excitation with the walls of the tube. This mechanism restricts the maximum achievable power output to ca. 50 mW, because of the need to depopulate the metastable neon atoms by wall collisions.

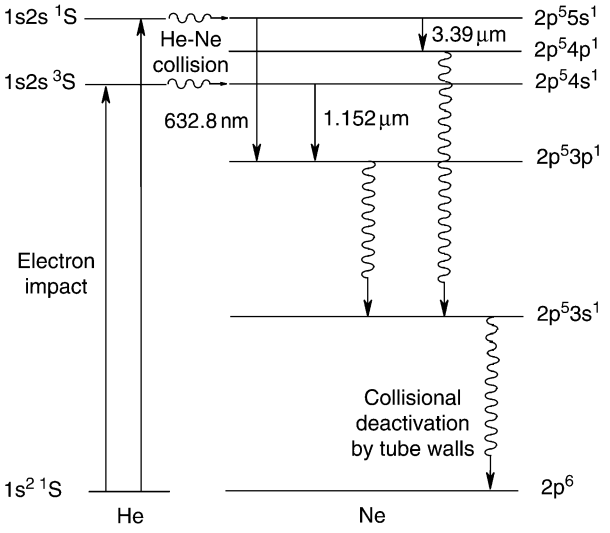

Figure 4 Energy levels of the He-Ne laser.

An advantage of using helium-neon lasers for Raman spectroscopy is that they generally operate in the fundamental TEM_{00} mode, which is critically dependent on the ratio of the length of the tube to its diameter. For this reason they are designed to have small tube diameters of around a few millimetres and lengths of 0.15–0.50 m, the small diameter also aiding collisional de-activation with the walls due to the relatively large surface to volume ratio of the tube. Another advantage of this laser for Raman spectroscopy is that the linewidth of the 632.8 nm emission line is ca. 1.5 GHz.

A disadvantage of the helium-neon laser is that it emits a large number of spontaneous emission lines originating from the excited neon atoms. These plasma emissions are observed in the Raman spectrum as sharp lines unless they are filtered out, for example, by a pre-monochromator or an interference filter. It should be mentioned, in passing, that these plasma lines are not always unwanted, because they can be very useful for wavenumber calibration of the Raman spectrometer.

The low output power of <50 mW is not generally a disadvantage for Raman microscopy since higher laser powers can often cause photolytic or thermal degradation of the sample. This is due to the high irradiance at the sample when the laser light is focused to a tight spot by the microscope objective. The excitation wavelength of 632.8 nm is suitable for combined use of the laser with a silicon-based CCD

detector in Raman spectroscopy, because large Stokes shifts in the 3000–4000 cm^{-1} region lie well within the quantum efficiency curve of this detector. It is also possible, though less common, to operate the helium-neon laser on weaker transitions that include the green 543.5 nm line.

Argon Ion Laser

The argon ion laser was one of the first lasers to be discovered following the invention of the laser and up until now it has been used extensively for Raman spectroscopy, among many other applications. Excitation is provided by a continuous electrical discharge, and because of the high energy required to ionize the argon atoms and then promote the ions to an excited state, the efficiency of the laser is very small (ca. 0.1%). In spite of this, once population inversion has been achieved, the gain of the laser is very high and output powers of up to 25 W can be obtained for the strong lines at 488.0 and 514.5 nm and up to 50 W for multiline operation.

An advantage of the argon ion laser is that it can provide emission at more than 35 discrete wavelengths, the strongest of which are listed in Table 1. These lie in the green, blue, and near ultraviolet regions of the spectrum, a number of the ultraviolet lines only being obtained on the larger frame argon ion lasers. Discrete laser emission lines are selected by tuning a prism or grating inside the cavity. The argon ion laser can also be operated in multiline mode, for example, for pumping dye or Ti:sapphire lasers.

514.5	2400
528.7	420

The five lines below 260 nm are frequency doubled.

The linewidths of the argon ion emission lines at 488.0 and 514.5 nm are around 4.0 GHz. The high temperature laser tube has a diameter of approximately 12 mm and a length in the range of 0.1 to 1.8 m. A 240 V three phase power supply and ca. 35 A are required for pumping a medium power 5 W argon ion laser. The tube also requires water cooling at a flow rate of ca. 10 L/min and a pressure of 25 psi because of the large amount of heat dissipation.

For Raman microscopy smaller, air-cooled argon ion lasers, which only require a 240 V single phase power supply, can be used to provide output of a few hundred milliwatts on the 488.0 and 514.5 nm lines. For this application, the excitation is provided by argon ion lasers, which are designed to operate in the TEM_{00} mode.

Until recently, the argon ion laser has been a workhorse as the most common excitation source for Raman spectroscopy, but it is now losing ground to solid state lasers. The principle reasons for this are that the latter are much more efficient and consequently do not in general have three phase power and water-cooling requirements. Nevertheless, argon ion lasers still have a niche when high excitation powers on the order of watts are required in conjunction with a good beam quality ($M^2 < 1.1$), for example, for Raman spectroscopy of gaseous samples. Another advantage of argon ion lasers over solid state lasers is their multiline capability.

Krypton Ion Laser

The krypton ion laser has useful discrete emission lines in the near ultraviolet, blue, yellow, red, and near infrared regions of the electromagnetic spectrum; the strongest lines of a Coherent Inc. Innova 400 krypton ion laser are listed in Table 2.

The argon ion and krypton ion lasers are close relatives, thus the large frame krypton ion laser has similar power and water-cooling requirements to those mentioned above for the argon ion laser. Also, like the argon ion laser, air-cooled models with lower power output are available. The characteristics of the two lasers are also similar; for example, the linewidths of the krypton ion transitions at 530.9, 568.2, and 647.1 nm are about 4.0 GHz, the laser tube has similar dimensions (0.1–2.0 m in length) and the laser can be operated in either TEM_{00} or multimode.

The krypton ion laser is even less efficient than the argon ion laser, consequently lower-power outputs of

up to about 20 W can be achieved when operated in multiline mode.

Mixed argon and krypton ion laser tubes are also commonly used that provide laser lines originating from both argon ion and krypton ion transitions. As with the individual argon ion and krypton ion lasers, sharp plasma lines, due to spontaneous emission from the rare gas ions, are observed in the Raman spectrum unless they are filtered out. If interference filters are used for this, each laser line requires its own filter that is tailored to the specific emission wavelength.

HeCd Laser

Laser lines at 325 and 442 nm, both capable of providing milliwatts of output power, can be obtained from the helium-cadmium laser. These emission lines result from electronic transitions in free cadmium atoms.

It is obviously advantageous to use blue, rather than longer wavelength, excitation (e.g., provided by the 442 nm line of the HeCd laser) for off-resonance Raman spectroscopy, due to the ν^4 dependence of the Raman light scattering efficiency, provided that the efficiencies of the illumination/collection optics and Raman spectrometer throughput are optimized in the blue region of the spectrum. Unfortunately, far more samples fluoresce when excited with blue light than with red or near infrared radiation, which explains why red or near infrared lasers (e.g., HeNe, semiconductor lasers) are more commonly used for general Raman applications.

Near Infrared Lasers

Although the traditional laser systems for Raman spectroscopy have been the argon ion, krypton ion, and helium-neon lasers for discrete excitation wavelengths, the diode laser has gained popularity over recent years.

The principal advantage of near infrared semiconductor lasers for Raman microscopy is that they generally excite less fluorescence in the Raman spectrum than visible lasers due to their longer wavelength. Commonly available wavelengths are 670, 785, 830, and 852 nm and, of these, the first two can be used in conjunction with silicon-based CCD detectors to give Stokes Raman shifts over the whole range of fundamental vibrations, up to 4000 cm^{-1}. However, for excitation wavelengths of 830 and 852 nm, only Stokes Raman bands in the fingerprint region can be detected with a silicon-based CCD detector because higher wavenumber Raman shifts approach the bandgap of the silicon semiconductor ($\lambda >$ ca. 1050 nm).

The disadvantages of diode lasers are that they cannot supply high power of narrow linewidth in single-mode and they are susceptible to mode hopping which gives rise to a shift in the excitation wavelength. This latter drawback is particularly disadvantageous for Raman spectroscopy because it results in a shift in the wavenumber positions of the Raman bands. When good beam quality is not required, broad stripe, high power laser diodes can be used; these can have output powers that are greater than 1 W but their emission linewidths are equal to ca. 2 nm, which is far too wide for Raman spectroscopic applications. These laser diodes find applications as pumps of solid state lasers, for example, Nd:YAG, Nd:YVO_4 lasers, however. Additionally, amplified stimulated emission (ASE) gives an unwanted background signal that can be very broad (ca. 20–30 nm) and 0.1–1% of the intensity of the laser line. This necessitates the use of bandpass filters in order to reduce this unwanted background.

Although laser diodes having an output of less than 200 mW can operate in TEM_{00} and in single longitudinal modes, mode hopping can occur due to optical feedback or fluctuations in environmental factors and this causes severe broadening of the linewidth. The sensitivity to optical feedback can be greatly reduced, hence the laser linewidth can be narrowed appreciably, by confining the frequency of the photons either in an internal cavity containing a small diffraction grating or in an external cavity. The former types of laser are sometimes called 'distributed feedback' (DFB) lasers because the feedback is distributed over the length of the grating, rather

than occurring all at once at a mirror. The wavelength that is fed back is determined by the period of the grating. Usually, a DFB laser has a grating fabricated into the entire length of the laser. A variation referred to as a distributed Bragg reflector (DBR) laser has a distinct grating fabricated into the substrate on each side of the active area. The external cavity semiconductor laser (ECSL) is fabricated by placing the laser diode in a separate resonator like a conventional gas or solid-state laser. The DBR and ECSL lasers are now discussed.

Distributed Bragg Reflector Lasers

The DBR laser consists of a grating on each side of the active region (Figure 5); these gratings act as mirrors having a reflectivity that is optimized at one particular wavelength, in addition to narrowing the laser linewidth. At present, DBR lasers are only commercially available having an excitation wavelength of 852 nm.

The emission linewidth is less than 4 MHz, which is suitable for the vast majority of Raman spectroscopic applications and the laser operates in single TEM_{00} mode. The disadvantages of DBR lasers are that the maximum output power is restricted to around 150 mW, so an optical isolator is usually necessary in order to prevent external facet damage caused by external optical feedback, and only an excitation wavelength of 852 nm is currently available.

External-Cavity Semiconductor Lasers (ECSL)

ECSLs provide higher output power (up to ca. 1 W) and a wider range of excitation wavelengths (630 nm to around 850 nm), as well as being less expensive than DBR lasers. They use the semiconductor chip only as the gain medium and employ an external grating, both as the frequency selector and the reflective mirror. Specific excitation wavelengths are becoming widely adopted in Raman microscopy employing single grating spectrograph in conjunction with CCD detection, such as 670, 785, 830, and 852 nm. The ECSLs have emission linewidths as low as a few MHz, but in general they span the range 2 MHz–30 GHz, and can operate in a nearly diffraction-limited transverse mode.

Three different cavity designs employing a diffraction grating have been discussed in the literature: Littrow type-I, Littrow type-II, and Littman configurations. In the Littrow type-I design, the laser diode light is incident on the grating at an angle of incidence equal to θ_{Littrow} (Figure 6a). The diffracted light in first order is re-directed back to the laser diode to provide feedback and the output is the zeroth order (i.e., specularly reflected) light. A disadvantage of this design is that the bandwidth of the grating is relatively large because a single pass geometry is used. In the Littrow type-II design, light from the rear facet of the laser diode is collimated by a lens and directed on to a grating at an angle of incidence equal to θ_{Littrow} (Figure 6b). The diffracted light in first order is re-directed back to the laser diode, in a similar fashion to the Littrow type-I design, in order to provide optical feedback, and the output is the laser light emitted from the front facet. Disadvantages of the Littrow type-II design are the requirement for

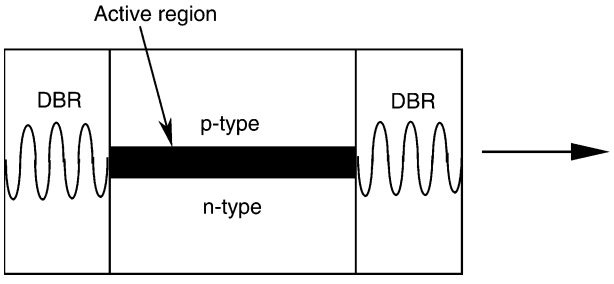

Figure 5 Diagram of the cavity of the DBR laser (adapted from Pan M-W, Benner RE and Smith LM (2002) Continuous lasers for Raman spectrometry. In: Chalmers JM and Griffiths PR (eds) *Handbook of Vibrational Spectroscopy*, 1. Chichester, UK: Wiley).

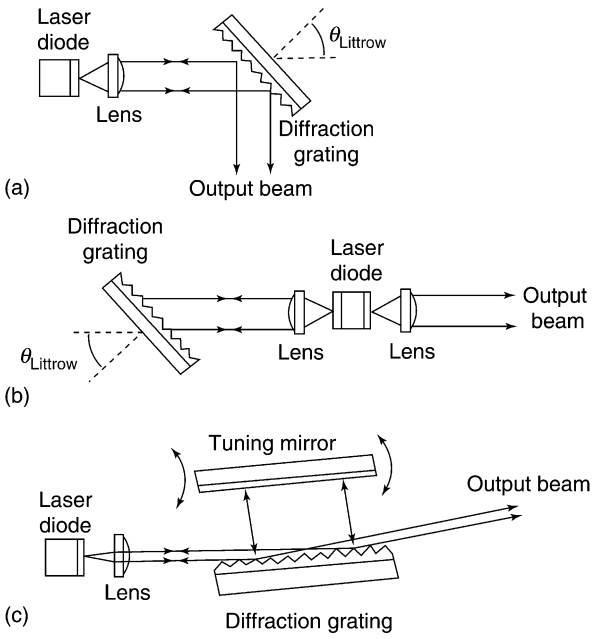

Figure 6 Diagrams of the cavities of (a) Littrow type-I, (b) Littrow type-II, and (c) Littman external cavity diode lasers (adapted from Pan M-W, Benner RE and Smith LM (2002) Continuous lasers for Raman spectrometry. In: Chalmers JM and Griffiths PR (eds) *Handbook of Vibrational Spectroscopy*, 1. Chichester, UK: Wiley).

custom fabrication of antireflection coatings on both facets and the sensitivity to external optical feedback. In the Littman design, the laser diode light is collimated by a lens and directed on to a grating at a grazing angle of incidence. The diffracted light is reflected by a mirror and diffracted back to the laser diode by the grating in order to provide optical feedback (Figure 6c). An advantage of this design is that the grating bandwidth is less than half that of the Littrow designs due to the double pass geometry, but a disadvantage is that the external cavity length is longer, resulting in a narrower spacing of the cavity modes. Another advantage of this design is that the tuning is accomplished by rotating the mirror instead of the grating, thus the alignment of the output beam is not altered when tuning. For Littrow type I and II and Littman ECSL designs, filtering of the ASE is required, as it can have an intensity of ca. 0.1 to 1% of the intensity of the laser line. Thus, these designs necessitate the incorporation of a bandpass filter (having a rejection of better than 10^{-4} at the ASE).

Nd:YAG Laser

Under normal conditions, the Nd:YAG laser oscillates on a transition in the near infrared at 1064 nm, and this is the excitation line that is used in most commercial Fourier Transform Raman spectrometers. The gain medium is a crystal of yttrium aluminium garnet ($Y_3Al_5O_{12}$, YAG) doped with ca. 1.0 mol% Nd^{3+} cations that substitute Y^{3+} ions in the cubic YAG lattice.

The Nd:YAG laser is a four-level system (Figure 7), which has high gain and low threshold due to the narrow fluorescent linewidth of the laser transition. Absorption bands of the Nd^{3+}ions around 808 nm conveniently match the energy of commercially available high-power multimode diode lasers that serve as the pump. The Nd^{3+} ions decay nonradiatively to the upper laser level, the $^4F_{3/2}$ state, thereby creating a population inversion. This is because the lower laser level, the $^4I_{11/2}$ state, has no appreciable thermal population at room temperature, since it is $>2000\ cm^{-1}$ above the $^4I_{9/2}$ ground state, and the $^4F_{3/2}$ excited state has a relatively long lifetime of 230 μs.

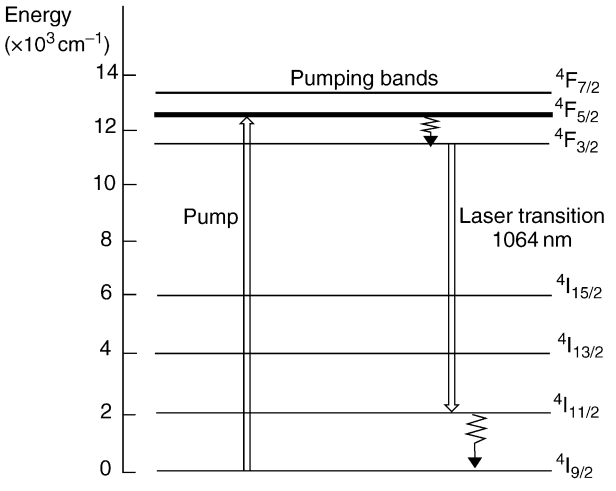

Figure 7 Energy levels of the Nd:YAG laser.

The high thermal conductivity of Nd:YAG enables the laser to operate at high power in either continuous wave (CW) or *Q*-switched modes, and the diode pumped solid state (DPSS) variety of the cw Nd:YAG laser can currently achieve an output power in excess of 20 W on the 1064 nm line. The laser can be designed to operate in the fundamental TEM_{00} mode and the full width at half maximum (FWHM) linewidth of the spontaneous emission of the 1064 nm laser transition is 120 GHz (ca. 0.45 nm). Advantages of the diode pumped Nd:YAG laser are that it is air-cooled and can be operated at 240 V single phase. Also, being all solid state and having a small footprint, it is robust and portable. The lifetime of the laser is dependent on the laser diodes used for pumping, but some Nd:YAG laser designs enable these to be replaced in the field.

The frequency-doubled Nd:YAG laser emitting green light, having a wavelength of 532 nm, is also commonly used nowadays for dispersive Raman spectroscopy, and an output power of 10 W on the 532 nm laser line is provided by commercially available frequency-doubled diode-pumped Nd:YAG lasers.

It is worth mentioning that Nd:YAG lasers have also been fabricated that emit either at 946 or 1330 nm, by suppressing the strong emission at 1064 nm and optimising the optics for the desired wavelength.

Nd:YVO_4 and Nd:YLF Lasers

An intracavity, frequency-doubled DPSS Nd:YVO_4 laser has recently become commercially available, and it has some advantages over the Nd:YAG laser including a larger stimulated emission cross-section and a higher absorption coefficient (along the extraordinary direction of the birefringent crystal). It has the same emission wavelength as the frequency-doubled Nd:YAG laser, i.e., 532 nm, and Nd:YVO_4 is the material of choice for cw end-pumped lasers having around 5 W output power. This is because the diode laser pump beam is tightly focused in the end-pumped system, but a small waist diameter cannot be retained over a distance of more than a

few millimeters, consequently a high absorption coefficient and gain are very beneficial.

The gain medium of the Nd:YLF laser consists of a crystal of yttrium lithium fluoride (YLF) that is doped with Nd^{3+} ions on the Y^{3+} cation sites. Unlike the Nd:YAG and Nd:YVO_4 lasers, the emission does not occur at 1064 nm; instead the $^4F_{3/2}-{}^4I_{11/2}$ emission occurs at wavelengths of either 1047 or 1053 nm, depending on the polarization that is selected. The former is due to extraordinary polarized light, whereas the latter is due to ordinary polarization, and either of these emission wavelengths can be selected using an intracavity polarizer. The Nd:YLF laser can offer benefits in *Q*-switched operation when the longer fluorescence lifetime (480 μs) of Nd^{3+} ions in the $^4F_{3/2}$ state enables a higher energy to be stored for the same number of pump laser diodes.

Ti:Sapphire Laser

The Ti:sapphire laser is tunable over the approximate range of 670–1070 nm with the peak of the gain curve at ca. 800 nm. In the gain medium, ca. 0.1% by weight Ti^{3+} is doped into a crystal of sapphire grown by the Czochralski method. The Ti^{3+} ions substitute for Al^{3+} ions in the Al_2O_3 of the sapphire and the laser emission is due to the $^2E-{}^2T_2$ transition of the Ti^{3+} cation, which has a $3d^1$ valence electronic configuration (Figure 8). The laser has a large stimulated emission cross-section but the fluorescence lifetime of the upper laser level (^2E state) is quite short (3.2 μs), thus the laser is usually laser (e.g., by argon ion or frequency-doubled Nd:YAG or Nd:YVO_4 lasers) rather than flashlamp pumped because a very high pump flux is required.

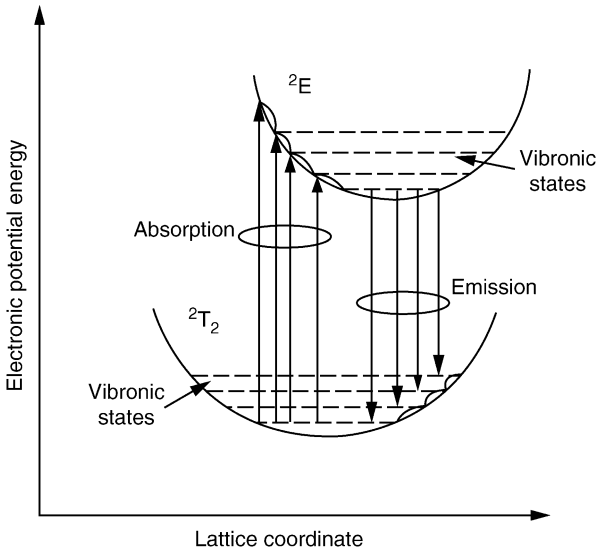

Figure 8 Energy levels of the Ti:sapphire laser (adapted from Pan M-W, Benner RE and Smith LM (2002) Continuous lasers for Raman Spectrometry. In: Chalmers JM and Griffiths PR (eds) *Handbook of Vibrational Spectroscopy*, 1. Chichester, UK: Wiley).

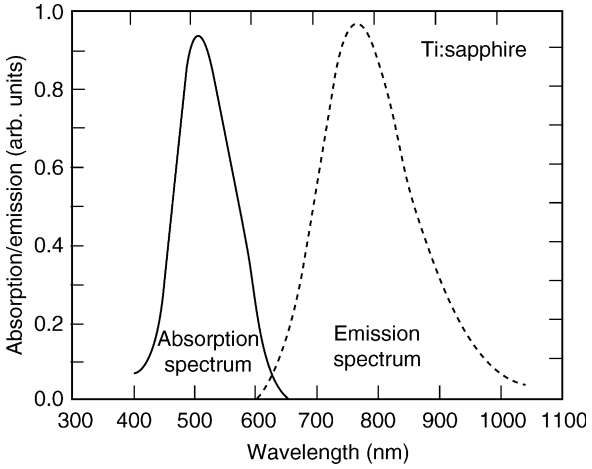

Figure 9 Absorption and emission spectra of the Ti^{3+} ion in sapphire. Al_2O_3 (adapted from Pan M-W, Benner RE and Smith LM (2002) Continuous lasers for Raman Spectrometry. In: Chalmers JM and Griffiths PR (eds) *Handbook of Vibrational Spectroscopy*, 1. Chichester, UK: Wiley).

The absorption and emission bands are broad and widely separated, due to the vibronic coupling between the Ti^{3+} host and the Al_2O_3 lattice (Figure 9). The lower laser level is any one of the vibronic levels of the $^2T_2$ state. Following the laser transition, the Ti^{3+} ions decay from the upper vibronic levels of the $^2T_2$ state down to the lower vibronic levels. Hence, this is a four-level laser.

The broad spontaneous emission linewidth of the $^2E-{}^2T_2$ laser transition is around 100 THz, the ouput power can be as high as 50 W, and the laser can be operated in either TEM_{00} or multimodes.

UV Lasers

UV laser sources offer numerous advantages over visible laser sources for Raman spectroscopy. A major consideration is that many analytes have absorptions in the near UV, making them amenable to resonance Raman spectroscopic studies. The signal enhancement (up to 10^6), that can be achieved in resonance Raman spectra, results in a large increase in detection sensitivity. Furthermore, some vibrational modes, which normally give rise to weak bands in the off resonance Raman spectrum, can show strong enhancement in the UV excited resonance Raman spectrum. A good example of this is the amide II band of peptides and proteins, which is due to a combination of N–H in plane bending and C–N stretching modes of the peptide linkage. This band is normally weak in the Raman spectrum but strong in the infrared spectrum; however, the amide II band

can show strong enhancement in the UV excited resonance Raman spectrum and this can be useful for determining secondary structure in proteins. A further benefit of UV excited Raman spectroscopy is that fluorescence can often be avoided as it tends to occur at a lower energy, outside the Stokes Raman spectral window.

It can be advantageous to use cw rather than pulsed excitation for UV resonance Raman spectroscopy, if the analyte has a long excited state lifetime relative to the pulsewidth of the pulsed laser. This is because the concentration of analyte molecules in the ground state is significantly depleted during pulsed excitation, due to Raman saturation giving a lower signal to noise ratio in the Raman spectrum than for the case of cw excitation. It has been found that pulse energy flux densities should be less than 1 mJ/cm^2 and flowing or spinning samples should be used, in order to ensure that nonlinear phenomena and saturation effects do not occur.

For UV Raman microscopy, where the laser beam is focused into a small spot of micrometer dimensions on the sample, it is essential to avoid using pulsed lasers delivering high peak powers. This is because such pulsed lasers can cause dielectric breakdown, and even at lower peak powers they can cause nonlinear effects and Raman saturation phenomena. Consequently, with UV Raman microscopy, one is restricted to the use of cw or quasicontinuous laser excitation.

It is only recently that high thoughput UV Raman microspectrometers have been developed. It has been demonstrated for visible Raman spectroscopy that a significantly higher throughput can be achieved by employing a single stage spectrograph with a notch filter instead of a double or triple monochromator. In the UV region, blocking the Rayleigh scattering is a problem because notch filters are not currently available. However, it has been discovered that this can be overcome by introducing two modifications to the design of the optical layout of a visible Raman microscope. First, two novel dielectric longpass filters were used instead of a notch filter in order to reject the elastically scattered light. Second, an all-reflecting Cassegrain microscope objective was used, instead of a lens, in order to block the specular reflection, and thereby further reduce the Rayleigh scattering background. These design modifications have enabled a single stage spectrograph with a holographic grating to be used to disperse the Stokes Raman radiation in a UV Raman microspectrometer (Figure 10).

In the optical layout of Figure 10 it can be seen that the laser excitation is not focused by the Cassegrain microscope objective because an epi-illumination configuration is not employed. Instead the laser is

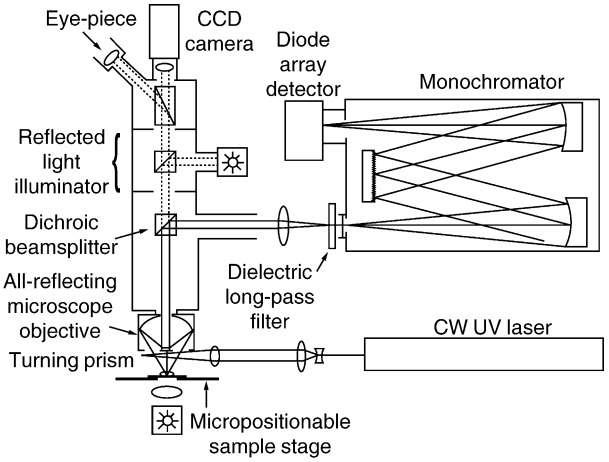

Figure 10 Diagram of the optical layout of a UV Raman microscope (adapted from Pajcini V, Munro CH, Bormett RW, Witkowski RE and Asher SA (1997) UV Raman microspectroscopy: Spectral and spatial selectivity and simplicity. *Applied Spectroscopy* 51: 81–86).

focused by a separate lens and directed on to the sample with a turning prism located directly underneath the Cassegrain objective. This minimizes loss of laser beam throughput or scattered light throughput to the spectrometer at the expense of spatial resolution, since the laser light is focused by a longer focal length lens than the microscope objective. An additional difference between the optical layouts of the visible and UV Raman microscopes shown in Figures 1 and 10, respectively, is that pinhole spatial filters are not shown in the latter. However, better axial spatial resolution could be achieved if this UV Raman microscope was made confocal by introducing a pinhole and lens.

Frequency-Doubled Argon Ion Laser

The frequency doubled argon ion laser is a popular choice among UV laser sources. The cw UV laser contains a nonlinear optical beta-barium borate (BBO) crystal, which is located within the laser cavity; this crystal frequency doubles the strong Ar^+ lines to give five UV lines below 260 nm which are listed in Table 1 for the Coherent Inc. Innova 300 Ar^+ ion laser system. Of these UV lines, the 228.9 nm line is almost ideal for resonance Raman enhancement of tyrosine and trpytophan residues in proteins and the 244.0 nm line is well suited for studying tyrosinate groups. The 244.0 nm line has also been used to excite selectively UV resonance Raman spectra from spatially resolved areas of biological samples within the nucleus of a single cell, from DNA in particular, using low laser powers and short acquisition times to keep sample damage to a minimum under the microscope.

Frequency-Doubled Krypton Ion Laser

Like the cw frequency-doubled argon ion laser mentioned above, the cw frequency-doubled krypton ion laser contains a nonlinear optical BBO crystal, which is located within the laser cavity; this crystal frequency doubles the strong Kr^+ lines to give 206.5 and 234 nm UV lines which are listed in Table 2 for the Coherent Inc. Innova 400 Kr^+ ion laser system. The 206.5 nm laser line is useful for exciting resonance Raman spectra within the $\pi-\pi^*$ amide transition of the peptide backbone of proteins, and the enhanced protein amide vibrational bands can be used to determine the protein secondary structure.

HeCd Laser

The 325 nm HeCd excitation line, in the near ultraviolet, can be used for combined micro-Raman/photoluminescence studies of, for example, semiconductors. These lasers are suitable for low-power applications, typically having output powers in the 1–100 mW range, and they can be designed to operate in TEM_{00} single-mode or multimode.

Quasi-CW Mode-Locked Ti:Sapphire Laser

The second harmonic of the mode-locked Ti:sapphire laser (ca. 350–500 nm), third harmonic (ca. 233–333 nm), and fourth harmonic (ca. 200–250 nm), are all available with conventional nonlinear crystals.

Typically, the Ti:sapphire crystal is pumped by a cw argon ion laser, for example, as the excitation source for a UV Raman microscope. This quasicontinuous laser system produces 2–3 ps pulses at a 76 MHz repetition rate and is continuously tunable over the 200–300 nm range. The typical power output is ca. 50 mW at 250 nm, ca. 10 mW at 240 nm, and 1 mW at 230 nm. In future, it is anticipated that a frequency-doubled Nd:YAG laser will be increasingly favored as the pump, creating an all-solid-state laser source.

Conclusions

Laser systems for Raman microscopy have been described in this article. Although the differences in the terms 'Raman spectroscopy' and 'Raman microscopy' only refer to whether a macro or micro sampling configuration is used, this does have a bearing on the types of laser systems that are employed. This is because the latter imposes a restriction on using low duty pulsed lasers with high pulse peak power, as both spatial and temporal confinement of the laser excitation can lead to dielectric breakdown of the sample, nonlinear phenomena, or Raman saturation. Thus, for this reason, one is limited to cw lasers or quasi-cw lasers for Raman microscopy whereas there is no such restriction for Raman spectroscopy.

The quality of the laser beam, measured by the M^2 value or 'times diffraction limit' influences the ultimate spatial resolution that can be achieved in Raman microscopy.

In the visible region, argon ion, krypton ion, and frequency-doubled Nd:YAG lasers have good beam quality and high power, with helium-neon and helium-cadmium lasers also having good beam quality but lower power; this makes these lasers good light sources for visible Raman microscopy.

For FT Raman microscopy using Nd:YAG excitation, there is a lack of fluorescence interference from a wide variety of samples, but sensitivity and spatial resolution are compromised in comparison to visible dispersive Raman microscopy.

Red and near infrared semiconductor lasers operating in TEM_{00} single mode can have good beam quality, approaching that of gas lasers, but they are power limited. Obviously, when good beam quality is not necessary, for example, for optically pumping other laser sources, high-power diode lasers can be used in multimode operation. Solid state red and near infrared laser sources are becoming very popular for routine Raman microscopic analysis due to their compactness, robustness, and economical power consumption.

Another reason for the popularity of the red and near infrared diode laser sources for Raman microscopy is that fluorescence is less of a problem due to the lower energy of the light, compared to conventional green 514.5 nm excitation. Although there is a penalty, due to the dependency of the scattering efficiency on the ν^4 term, present day silicon-based CCD arrays can exhibit excellent detection quantum efficiency of Stokes shifted Raman radiation, across the whole vibrational spectrum, when using standard 670 and 785 nm diode lasers and, at least across the fingerprint region, when using 830 and 852 nm diode lasers.

For ultimate spatial resolution in the Raman microscopic experiment, short wavelength excitation is advantageous because it is fundamentally possible to focus to a smaller diffraction-limited laser spot. In this regard, it would be preferable to use UV Raman microscopy where fluorescence is also not as problematic as it is in the visible region. However, in spite of recent improvements in UV laser sources such as the intracavity frequency-doubled argon and krypton ion cw lasers, there are current instrumental limitations on the throughput efficiency of the UV Raman microscope imposed by the lack of availability of

suitable notch filters and low stray light and high throughput optics.

It is anticipated that in the future all-solid-state, quasi-cw, diode pumped, mode-locked Ti:sapphire lasers operating on their third or fourth harmonics will become increasingly popular for providing tunable UV excitation affording good beam quality. It is now also possible to fabricate hollow cathode metal ion deep UV lasers, 10–15 cm in length, 2–4 cm in diameter, weighing 50–100 g and requiring only 2–3 W of electrical power. These lasers have low beam quality (M^2 equal to ca. 18), but they make possible the development of portable UV fluorescence imaging and Raman microprobes for geobiological exploration of terrestrial and extraterrestrial environments.

Second-Harmonic Spectroscopy

Introduction

The demonstration of second-harmonic generation (SHG), one of the early experiments with pulsed lasers, is considered to have marked the birth of the field of nonlinear optics. The importance of second-harmonic generation, and the related phenomena of sum- and difference-frequency generation, as methods for producing new frequencies of coherent radiation was recognized immediately and has in no way diminished over the years. Associated with these applications came an interest in the fundamental nature of the second-order nonlinear response, and some spectroscopic studies were undertaken with this motivation. These investigations were of rather limited scope and were not developed as a general probe of materials. In contrast, the third-order nonlinear optical interactions have given rise to a panoply of significant spectroscopic measurement techniques, including, to name a few, coherent Raman spectroscopy, pump-probe and other four-wave mixing measurements, two-photon absorption and hole burning measurements, photon echoes, and Doppler-free spectroscopy.

A central factor in the lack of spectroscopic applications of the second-order nonlinear response lies in a fundamental symmetry constraint. Unlike the third-order nonlinearity, which is present in all materials, only materials lacking a center of inversion give rise to an (electric-dipole) allowed second-order nonlinear response. As we demonstrate in this article, however, it is this property that makes SHG, as well as the sum-frequency generation process discussed elsewhere in this encyclopedia, such a remarkable probe of surfaces and interfaces. For centrosymmetric materials, the second-order nonlinear response is strong only at interfaces, where only a monolayer or so of material contributes to the response. This yields a purely optical probe (with incident and emitted photons) that gives an inherent surface sensitivity comparable to the best electron spectroscopies, such as electron diffraction, Auger-electron spectroscopy, photoemission spectroscopy, and scanning tunneling microscopy, the workhorses of surface science. Neither linear nor third-order nonlinear optical measurements provide this inherent interface sensitivity. The possibility of probing interfaces by purely optical means permits one to take advantage of several important features of optical radiation. Perhaps most noteworthy is the possibility of probing buried interfaces of every sort, from solid/solid to liquid/liquid, as well as the more conventional cases of solid/vapor, liquid/vapor, and liquid/solid. In addition, laser-based techniques offer unequalled capabilities for spectral or temporal resolution.

In this article, we present a brief overview of SH spectroscopy for the study of surfaces and interfaces. The article is divided into two principal sections: an introductory section that presents some of the fundamentals of SHG and the behavior at interfaces; and a discussion of the different types of information that the method can yield, as illustrated by some representative examples. A brief section on the experimental technique links these two parts.

Fundamentals of Surface SHG

Basic Notions

Within the domain of classical optics, the response of a material to electromagnetic radiation is described by an induced polarization **P** that varies linearly with the electric field strength, **E**. This situation reflects the fact that the strength of electric fields for light encountered under conventional conditions is minute compared to that of the electric fields binding atoms and solids together. The electric field binding an atom may be estimated as $E_a \sim 1\ \text{V/Å} = 10^{10}\ \text{V/m}$. To reproduce this field strength by an electromagnetic wave requires an irradiance of $I_a \sim 10^{17}\ \text{W/m}^2$, so the validity of this linear approximation in classical optics is clear. The advent of the laser, with its capability for producing light beams with very high optical power and irradiance, has permitted us to

probe and exploit the nonlinear response of materials, giving rise to the field of nonlinear optics.

The next-order material response beyond the linear approximation consists of an induced nonlinear source polarization $\mathbf{P}^{(2)} = \varepsilon_0 \boldsymbol{\chi}^{(2)} : \mathbf{EE}$ that depends quadratically on the driving electric field $\mathbf{E}$, described by a second-order nonlinear susceptibility $\boldsymbol{\chi}^{(2)}$. For excitation by a single laser at a frequency ω, this response gives rise to SHG at a frequency of 2ω, as well as optical rectification with a dc induced-polarization. For beams at two distinct frequencies of ω_1 and ω_2, the processes of sum- or difference-frequency generation (SFG or DFG) become operative with the production of the new frequencies of $|\omega_1 \pm \omega_2|$. For a relationship of the given form, which assumes only a spatially local quadratic dependence of the polarization on the driving electric field, one can show that $\boldsymbol{\chi}^{(2)}$ must vanish within any centrosymmetric medium. This is a direct consequence of the fact that $\boldsymbol{\chi}^{(2)}$ as a quantity describing a centrosymmetric medium should not change under an inversion operation, while the quantities $\mathbf{P}^{(2)}$ and $\mathbf{E}$ as polar vectors will change sign. The interface specificity of the SHG technique for centrosymmetric media follows from this general observation: only at interfaces is the bulk symmetry broken and the SHG process allowed.

Anharmonic Oscillator Model

Before we embark on our discussion of surface SHG, we first briefly consider a simple classical model of SHG based on an anharmonic oscillator. Although this is not a realistic treatment of the response of materials, it helps to illustrate the characteristic features of the surface SHG process and its spectroscopic attributes. In the anharmonic oscillator model, the medium is treated as a collection of electrons bound to fixed ion cores. While the usual Lorentz model only includes the effect of a linear restoring force, to describe second-order response, we generalize this description to include a leading-order anharmonic restoring force. For simplicity, we consider motion of the anharmonic oscillator in one spatial dimension, in which case the classical equation of motion for the displacement, x, of the electron can then be written as

$$\frac{\mathrm{d}^2x}{\mathrm{d}t^2} + 2\gamma\frac{\mathrm{d}x}{\mathrm{d}t} + \omega_0^2 x - bx^2 = -\frac{e}{m}E(t) \qquad [1]$$

Here $-e$ and m denote, respectively, the electron charge and mass, and $E(t)$ is the optical driving field. The (angular) frequency ω_0 defines the resonance of the harmonic component of the response, and γ represents a phenomenological damping rate for the oscillator. The nonlinear restoring force corresponds to the term containing the parameter b, a material-dependent constant. We are interested in the solution of this equation for a monochromatic driving field at frequency ω with amplitude $E(\omega)$ which we write as

$$E(t) = E(\omega)\exp(-\mathrm{i}\omega t) + \text{c.c.} \qquad [2]$$

An exact solution to eqn [1] in the presence of this electric field is not possible. Let us, however, consider a regime in which we do not excite the oscillator too strongly, and the effect of the anharmonic term remains relatively small compared to the harmonic one. In this case, we may solve the problem perturbatively in powers of the driving field. We find a linear response at the fundamental frequency and a nonlinear response at the SH frequency, which we can write in terms of the corresponding induced dipole moments $p = -ex$:

$$p(t) = p^{(1)}(\omega)\exp(-\mathrm{i}\omega t) + p^{(2)}(2\omega)\exp(-\mathrm{i}2\omega t) + \text{c.c.} \qquad [3]$$

We can then write the amplitudes for the harmonically varying dipole moments as

$$p^{(1)}(\omega) = \alpha^{(1)}(\omega)E(\omega) \qquad [4]$$

$$p^{(2)}(2\omega) = \alpha^{(2)}(2\omega = \omega + \omega)E(\omega)E(\omega) \qquad [5]$$

where $\alpha^{(1)}$, the linear polarizability, and $\alpha^{(2)}$, the second-order polarizability (or first hyperpolarizability) for SHG are given, respectively, by

$$\alpha^{(1)}(\omega) = \frac{e^2}{m}\frac{1}{D(\omega)} \qquad [6]$$

$$\alpha^{(2)}(2\omega = \omega + \omega) = \frac{(e^3/m^2)b}{D(2\omega)D^2(\omega)} \qquad [7]$$

Here we have introduced the resonant response at the fundamental frequency by $D(\omega) \equiv \omega_0^2 - \omega^2 - 2\mathrm{i}\gamma\omega$, with a corresponding relation for the response $D(2\omega)$ at the SH frequency. A similar derivation can, of course, be applied to obtain the corresponding material response for the SFG or DFG processes.

The spectral dependence of the polarizabilities $\alpha^{(1)}$ and $\alpha^{(2)}$ is illustrated in Figure 1 for the anharmonic oscillator model with a resonance frequency of ω_0. In the linear case, one sees the expected behavior of the loss, associated with the $\mathrm{Im}[\alpha^{(1)}]$, and dispersion associated with $\mathrm{Re}[\alpha^{(1)}]$. A single resonance in the linear response is seen for the driving frequency ω near the oscillator frequency ω_0. For the case of SHG, on the other hand, we observe both resonances when the fundamental frequency $\omega \approx \omega_0$ and when the SH

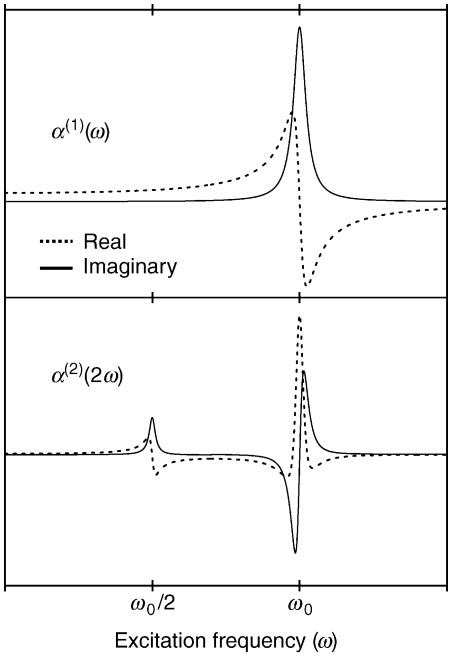

Figure 1 Real and imaginary components of the linear polarizability $\alpha^{(1)}(\omega)$ (top panel) and the second-order nonlinear polarizability $\alpha^{(2)}(2\omega = \omega + \omega)$ (bottom panel) plotted versus frequency according for the anharmonic oscillator model. For the SH response, the resonance features at $\omega = \omega_0$ and $\omega = \omega_0/2$ correspond, respectively, to single-photon and two-photon resonances.

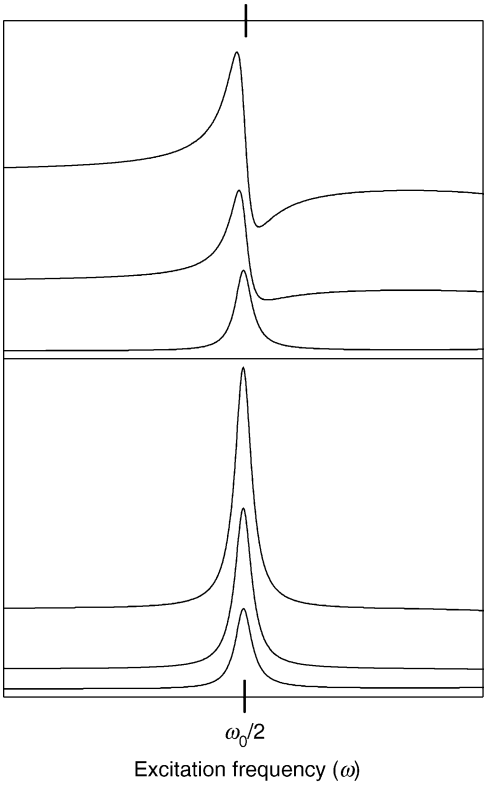

Figure 2 SH spectra $I(2\omega)$ versus pump laser frequency ω corresponding to Figure 1 in the vicinity of the two-photon resonance, with and without the presence of a nonresonant (frequency-independent) background: $I(2\omega) \sim |\alpha^{(2)}(2\omega = \omega + \omega) + k|^2$, where k represents a constant background and parametrized through $k = m|\alpha^{(2)}(2\omega = \omega_0)|$ and m is constant factor. Top panel: $m = 0$, 0.5, 1 (bottom to top curves). Bottom panel: $m = 0$, $0.5i$, i (bottom to top curves). In the top panel, the upper two lineshapes were displaced vertically to distinguish the three curves.

frequency $2\omega \approx \omega_0$. In quantum mechanical language introduced below, these peaks can be considered as arising, respectively, from matching of the fundamental and second-harmonic photon energies with the transition energy in the material.

In SHG spectroscopy, one normally measures the SH power as a function of the laser frequency. The SH field will scale with the nonlinear material response, i.e., with $\alpha^{(2)}(2\omega = \omega + \omega)$, so that the SH power will be proportional to $|\alpha^{(2)}(2\omega = \omega + \omega)|^2$. Figure 2 shows the corresponding spectra in the vicinity of the second-harmonic resonance. An important aspect of this type of spectroscopy, which is also present in other nonlinear spectroscopies, such as coherent Raman measurements, is the role that may be played by a nonresonant background. This may arise either from the off-resonant response of the system under study or from a coherent background from another material. In either case, the effect can be described by adding a spectral flat background response to the nonlinearity. Now when we detect the optical power, we then measure a quantity proportional to $|\alpha^2(2\omega = \omega + \omega) + k|^2$, where k represents the nonresonant background. The presence of k obviously elevates the baseline response near a resonance. In addition, however, depending on the relative phase of k, this extra term can introduce significant changes in the observed lineshapes. Figure 2 illustrates this effect, which must always be borne in mind in the interpretation of experimental spectra.

For the purposes of studies of surfaces and interfaces, the key property of second-order nonlinear processes is the fact that they exhibit, for centrosymmetric bulk media, an inherent interface specificity. This feature can be readily understood in the context of the nonlinear oscillator model in which the SH polarization scales with the material parameter b. Since this term is associated with a potential that varies as x^3, it is clear that the value of the b parameter can be taken as a measure of the material's departure from inversion symmetry. At the interface, such a term can be present, reflecting the inherent

asymmetry at a boundary, while it must necessarily be absent in the bulk of a centrosymmetric material.

Quantum-Mechanical Description of SHG

A correct description of SHG naturally requires a quantum mechanical treatment of the material response to the optical field. For our present purposes, we consider a localized entity with a nonlinear response, such as a non-centrosymmetric molecule at a surface. We consider below how these individual units can be added together to yield the surface nonlinear response of the material. Within this picture, we write the induced nonlinear dipole moment $\mathbf{p}^{(2)}$ of each molecule in terms of the driving electric field $\mathbf{E}$ as

$$\mathbf{p}^{(2)}(2\omega) = \boldsymbol{\alpha}^{(2)}(2\omega = \omega + \omega) : \mathbf{E}(\omega)\mathbf{E}(\omega) \qquad [8]$$

This relation is simply the generalization of eqn [5] to include a full 3-dimensional description, where $\mathbf{p}^{(2)}$ and $\mathbf{E}$ are vectors and the second-order nonlinear polarizability $\boldsymbol{\alpha}^{(2)}$ is a third-rank tensor. The quantum mechanical description enters in how we relate the response function $\boldsymbol{\alpha}^{(2)}(2\omega = \omega + \omega)$ to the underlying properties of the material.

We can obtain an expression for the second-order nonlinear polarizability by application of second-order perturbation theory with the light–matter interaction treated as the perturbation. Within the electric-dipole approximation, the interaction Hamiltonian can be taken as $H_{\text{int}} = -\boldsymbol{\mu}\cdot\mathbf{E}(t)$, where $\boldsymbol{\mu} = -e\mathbf{r}$ denotes the electric-dipole operator and $\mathbf{E}(t)$ the electric field of the driving laser beam. Using the standard density-matrix formalism for second-order perturbation theory, one calculates for the Cartesian components $\alpha^{(2)}_{ijk}$ of the tensor $\boldsymbol{\alpha}^{(2)}$ as

$$\alpha^{(2)}_{ijk}(2\omega = \omega + \omega) = -\frac{1}{\hbar^2}\sum_{g,n,n'}\left[\frac{(\mu_i)_{gn}(\mu_j)_{nn'}(\mu_k)_{n'g}}{(2\omega - \omega_{ng} + i\Gamma_{ng})(\omega - \omega_{n'g} + i\Gamma_{n'g})} + \cdots\right]\rho^{(0)}_g \qquad [9]$$

In this expression, the letters g, n', and n represent energy eigenstates $|g\rangle$, $|n'\rangle$, and $|n\rangle$ of the system, with $\rho^{(0)}_g$ corresponding to the thermal population for differing available ground states g. As illustrated in Figure 3, the SHG process can be regarded as involving a series of three transitions: two transitions associated with the absorption of two pump photons, each of energy $\hbar\omega$, and a transition associated with emission of a second-harmonic photon of energy $2\hbar\omega$. These transitions occur through the electric-dipole operator $\boldsymbol{\mu}$ and are characterized by the matrix elements $(\mu_i)_{gn}$. In eqn [9], the energy denominators involve the energy differences $\hbar\omega_{ng} \equiv E_n - E_g$ and widths $\hbar\Gamma_{ng}$ for transitions between eigenstates $|n\rangle$ and $|g\rangle$, and similarly for other combinations of states. In addition to the term indicated explicitly in eqn [9], there are seven additional terms with different Cartesian coordinates in the matrix elements and/or frequency denominators.

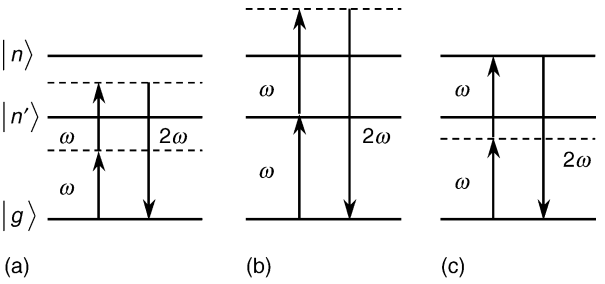

Figure 3 Quantum mechanical description of SHG process for the situations of (a) nonresonant, (b) single-photon resonant, and (c) two-photon resonant interactions. SHG occurs through transition from the initial state electronic state $|g\rangle$ and a first intermediate state $|n'\rangle$, then to a second intermediate state $|n\rangle$, followed by a return to the initial state. The process is just a parametric conversion of two photons at frequency ω into one photon at frequency 2ω.

The frequency denominators in the eight terms of eqn [9] introduce a resonant enhancement in the nonlinearity when either the fundamental frequency ω or the SH frequency 2ω coincides with a transition from a ground state $|g\rangle$ to one of the intermediate states $|n'\rangle$ or $|n\rangle$. Figure 3a shows the situation for a nonresonant nonlinear response, while Figures 3b,c illustrate, respectively, single- and two-photon resonances. The numerator in the perturbation theory expression consists of products of the three dipole matrix elements of the form $(\mu_i)_{gn}(\mu_j)_{nn'}(\mu_k)_{n'g}$. These terms reflect the structure and symmetry of the material that is built into the third-rank tensor $\alpha^{(2)}_{ijk}(2\omega = \omega + \omega)$.

The Surface Nonlinear Response

As a model of the surface nonlinearity, let us consider a monolayer of oriented molecules. The surface nonlinear response accessible to a macroscopic measurement is given, under the neglect of local-field effects, simply by summing the response of the individual molecules. The resulting surface nonlinear susceptibility tensor $\chi^{(2)}_{s,ijk}$ connecting the induced nonlinear sheet polarization to the driving electric field can then be expressed as

$$\chi^{(2)}_{s,ijk} = \frac{N_s}{\varepsilon_0}\langle T_{i\lambda}T_{j\mu}T_{k\nu}\rangle\alpha^{(2)}_{\lambda\mu\nu} \qquad [10]$$

Here N_s denotes the adsorbate surface density, $\alpha^{(2)}_{\lambda\mu\nu}$ the nonlinear polarizability of the molecule expressed in its own coordinate system, $T_{i\lambda}$ the transformation tensor from the molecule's coordinate system to the laboratory frame, $\langle\,\rangle$ an ensemble average over the orientation of the different molecules in the monolayer, and $\varepsilon_0 = 8.85 \times 10^{-12}$ F/m the permittivity of free space. This expression for the surface nonlinear susceptibility has been successful in describing properties of adsorbed molecules, including their coverage, orientation, and spectroscopic features.

For the surfaces of materials such as semiconductors or metals with delocalized electronic states, a somewhat different formulation of the nonlinear response is appropriate. A modified version of eqn [9] can be obtained using the relevant band states. The underlying concepts involved in the surface nonlinear response are, however, similar to those presented for the molecular case.

Regardless of the details of the model describing the surface nonlinear susceptibility, its tensor properties must reflect the symmetry of the interface. In that respect $\chi^{(2)}_{s,ijk}$ is quite analogous to the bulk nonlinear response, $\chi^{(2)}_{ijk}$, in a non-centrosymmetric medium. In the absence of any symmetry constraints, $\boldsymbol{\chi}^{(2)}_s$ will exhibit $3 \times 3 \times 3 = 27$ independent elements for SFG and DFG. For SHG, the order of the last two indices has no significance, and the number of independent elements is reduced to 18. If the surface exhibits a certain in-plane symmetry, then the form of $\boldsymbol{\chi}^{(2)}_s$ will be simplified correspondingly. For the common situation of an isotropic surface, for example, SHG possesses three allowed elements of $\boldsymbol{\chi}^{(2)}_s$ and may be denoted as $\chi^{(2)}_{s,\perp\perp\perp}$, $\chi^{(2)}_{s,\perp\parallel\parallel}$, $\chi^{(2)}_{s,\parallel\perp\parallel} = \chi^{(2)}_{s,\parallel\parallel\perp}$, where $\perp$ corresponds to the direction of the surface normal and $\parallel$ to an in-plane direction. The nonvanishing elements of $\boldsymbol{\chi}^{(2)}_s$ for other commonly encountered surface symmetries are summarized in several textbooks and reviews listed below.

Radiation Properties for Surface SHG

In order to probe and extract information from interfaces through surface SHG, it is necessary to understand how radiation interacts with the relevant media and gives rise to the experimentally observable signals. Here we present the principal results for the usual case of a spatially homogeneous planar interface. Nonplanar and inhomogeneous geometries, which are also of considerable interest, will be considered briefly under the heading of applications of the SHG technique below.

The SHG process is coherent in nature. Thus, for the planar geometry, a pump beam impinging on the interface will give rise to a well-collimated SH radiation emerging in distinct reflected and transmitted directions. To describe this situation in a more detailed fashion and provide formulas for the radiation efficiency, we introduce a general description of SHG by a planar interface excited by a plane wave, as shown in Figure 4. The nonlinear response of the interface described by the surface nonlinear susceptibility tensor $\boldsymbol{\chi}^{(2)}_s$ is incorporated through a nonlinear source polarization $\mathbf{P}^{(2)}$ of

$$\begin{aligned}\mathbf{P}^{(2)}(2\omega) &= \mathbf{P}^{(2)}_s(2\omega)\delta(z) \\ &= \varepsilon_0 \boldsymbol{\chi}^{(2)}_s(2\omega = \omega + \omega) : \mathbf{E}(\omega)\mathbf{E}(\omega)\delta(z) \qquad [11]\end{aligned}$$

localized at the interface ($z = 0$). In addition to the strong nonlinear response at the interface, one must also generally consider the nonlocal nonlinear response of the bulk media. This response is much weaker than the symmetry-allowed interfacial response, but is permitted even in centrosymmetric materials. Since it is present in a much larger volume, however, its cumulative effect, while generally weaker than the surface response, may be of comparable magnitude. For simplicity, however, we neglect this constant background response in our discussion in this article, but a complete discussion can be found in the referenced works. The overall SH response is naturally also influenced by the linear optical properties of the surrounding media. The two bulk media and the interfacial region are characterized, respectively, by frequency-dependent dielectric functions ε_1, ε_2, and ε', as shown in Figure 4. Again for simplicity, and in accordance with most applications, we take the linear response to be isotropic.

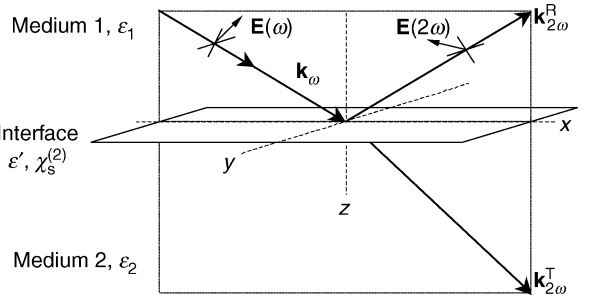

Figure 4 Schematic representation of SHG at the interface between two centrosymmetric media. The pump field $\mathbf{E}(\omega)$ at frequency ω with corresponding wavevector $\mathbf{k}_\omega$ is incident on the interface from medium 1. The SH field $\mathbf{E}(2\omega)$ at frequency 2ω is emitted in directions described by the wavevectors $\mathbf{k}^{R}_{2\omega}$ (reflected in medium 1) and $\mathbf{k}^{T}_{2\omega}$ (transmitted in medium 2). The linear dielectric constants of media 1, 2, and the interface are denoted, respectively, by ε_1, ε_2, and ε'. The nonlinear response of the interface ($z = 0$) is given by the surface nonlinear susceptibility tensor $\boldsymbol{\chi}^{(2)}_s$.

Figure 4 shows the incoming pump radiation and the reflected and transmitted SH beams. The directions of these beams are determined by conservation of the component of the momentum parallel to the interface in the SHG process, i.e., $2\mathbf{k}_{\omega,\parallel} = \mathbf{k}^{\mathrm{R}}_{2\omega,\parallel} = \mathbf{k}^{\mathrm{T}}_{2\omega,\parallel}$. Thus the reflected and transmitted beams both remain in the plane of incidence, with directions governed by the so-called nonlinear Snell's law. For bulk media without dispersion between the frequencies of ω and 2ω, the reflected and transmitted beams simply maintain the same angle of incidence as the pump beam. However, for dispersive bulk media, the directions of the beams are, however, altered, as can be understood immediately from the expression $2k_\omega/k_{2\omega} = n_\omega/n_{2\omega}$, where n denotes the refractive index of the medium. The surface SHG process does, nonetheless, differ in an important respect. In contrast to the situation for bulk media, the interfacial region is of negligible thickness, so phase shifts can obviously be disregarded. The issue of phase matching, which is of great significance for SHG from bulk media, consequently does not enter into the surface SHG problem.

By application of the Maxwell equations with the indicated nonlinear source polarization, one can derive explicit expressions for the SH radiation in terms of the linear and nonlinear response of the materials and the excitation conditions. For the case of the nonlinear reflection, the irradiance for the SH radiation can be written as

$$I(2\omega) = \frac{\omega^2 \sec^2\theta |\mathbf{e}'(2\omega)\cdot\boldsymbol{\chi}^{(2)}_{\mathrm{s}} : \mathbf{e}'(\omega)\mathbf{e}'(\omega)|^2 [I(\omega)]^2}{2\varepsilon_0 c^3 [\varepsilon_1(2\omega)]^{1/2}\varepsilon_1(\omega)} \quad [12]$$

where $I(\omega)$ denotes the irradiance of the pump beam at the fundamental frequency; c is the speed of light in vacuum; θ is the angle of emission of the SH beam with respect to the surface normal. The vectors $\mathbf{e}'(\omega)$ and $\mathbf{e}'(2\omega)$ represent the polarization vectors $\hat{\mathbf{e}}_1(\omega)$, and $\hat{\mathbf{e}}_1(2\omega)$, respectively, after they have been adjusted to account for the linear propagation of the waves to the interface. More specifically, we may write $\mathbf{e}'(\omega) = \mathbf{F}_{1\to 2}\hat{\mathbf{e}}_1(\omega)$. Here the $\mathbf{F}_{1\to 2}$ describes the relationship between the electric field $E\hat{\mathbf{e}}_1$ in medium 1 (propagating towards medium 2), which yields a field $E\mathbf{e}'$ at the interface. For light incident in the x–z plane as shown in Figure 4, $\mathbf{F}_{1\to 2}$ is a diagonal matrix whose elements are $F^{xx}_{1\to 2} = 2\varepsilon_1 k_{2,z}/(\varepsilon_2 k_{1,z} + \varepsilon_1 k_{2,z})$, $F^{yy}_{1\to 2} = 2k_{1,z}/(k_{1,z} + k_{2,z})$, and $F^{zz}_{1\to 2} = 2(\varepsilon_1\varepsilon_2/\varepsilon')k_{1,z}/(\varepsilon_2 k_{1,z} + \varepsilon_1 k_{2,z})$, where the quantity $k_{i,z}$ denotes the magnitude of the z-component of the wavevector in medium i at the relevant wavelength (ω or 2ω) (Figure 4).

A few observations may be made about eqn [12], which describes the relationship between the typical experimental observables of the pump irradiance, $I(\omega)$, and the irradiance of the emitted SH reflection, $I(2\omega)$, from the interface. First, one can immediately recognize the quadratic relationship between the pump irradiance and the SH irradiance that is expected for a second-order nonlinear optical effect. Second, the SH radiation is determined not only by the nonlinear optical response, but by the linear optical properties of the relevant media. Consequently, obtaining the surface nonlinear susceptibility tensor $\boldsymbol{\chi}^{(2)}_{\mathrm{s}}$ from experiment requires knowledge or measurement of the linear response. (It should be noted, however, that the interfacial linear properties always enter into the response in a fixed manner and can be incorporated into an effective surface nonlinear response.) The linear response can significantly enhance or reduce the efficiency of the SHG process. The use of a total-internal reflection geometry, for example, provides a significant enhancement in the SH radiation through the linear optical response of the media. Third, while full knowledge of the linear and nonlinear response will obviously allow one to predict the strength of the SH radiation for any set of conditions, a simple measurement of the SH response does not permit one to determine $\boldsymbol{\chi}^{(2)}_{\mathrm{s}}$, even if the linear optical properties are known. The determination of the tensor $\boldsymbol{\chi}^{(2)}_{\mathrm{s}}$ requires probing the material with different polarization states and/or angles of incidence. Protocols for making these measurements have been discussed extensively in the literature. For the general case of a material with in-plane anisotropy, such as the surface of a crystal, measurements of the response as the crystal is rotated about its surface normal are also very useful in a complete determination of $\boldsymbol{\chi}^{(2)}_{\mathrm{s}}$. Fourth, the simple measurement of the SH intensity as assumed here obviously eliminates information about the overall phase of the $\boldsymbol{\chi}^{(2)}_{\mathrm{s}}$. This phase information is often of considerable interest and importance. For example, if the response of the interface is dominated by an oriented molecular monolayer, the sign of $\boldsymbol{\chi}^{(2)}_{\mathrm{s}}$ will be inverted if the monolayer is reflected through the plane of the surface, i.e., the phase of $\boldsymbol{\chi}^{(2)}_{\mathrm{s}}$ yields information on the polar ordering of the layer. To obtain such phase information, one must employ a scheme using interference with a known SH reference. This approach, which is sketched briefly in the next section, is implemented quite commonly in experiment.

Experimental Considerations

The merits of the SHG technique for selective probing of interfaces are clear. On the other hand, one needs

to be able to detect the optical signal associated with a second-order nonlinear response of a material that arises from an effective thickness of just a monolayer or so. Consequently, it is important to consider various factors that aid in optimizing the strength and detectability of the SH radiation. To discuss how best to achieve this end, let us recast eqn [12] in terms of more convenient experimental parameters. We express the SH signal, S, in units of photons/s and describe the laser excitation by its pulse energy E_p, pulse width τ, and repetition rate R. For irradiation of an area A of the sample, we then obtain

$$S = \frac{\omega \sec^2\theta E_p^2 R |\chi_{eff}^{(2)}|^2}{4\hbar\varepsilon_0 c^3 \tau A} \qquad [13]$$

where $|\chi_{eff}^{(2)}| \equiv |\mathbf{e}'(2\omega)\cdot\boldsymbol{\chi}_s^{(2)} : \mathbf{e}'(\omega)\mathbf{e}'(\omega)| / [\varepsilon_1^{1/2}(2\omega)\,\varepsilon_1(\omega)]^{\frac{1}{2}}$, whose typical value is of the order of 10^{-21} m^2/V. From this relation, we see that increasing either the pulse energy or repetition rate of the laser will enhance our SH count rate. These parameters are, however, often limited by the characteristics of the available laser, as well as possible damage of the sample. For a given pulse energy and repetition rate, the SH signal is also seen to increase as the laser pulse duration or sample area is decreased. In practice, adequate SH signals can generally be obtained from high-power Q-switched lasers (with nanosecond pulses) with a fairly large focal spot. A preferred solution in most cases is, however, provided by modelocked lasers with high repetition rate and pulses of sub-picosecond duration. Surface SH signals obtained, for example, using a femtosecond modelocked Ti:sapphire oscillator, are typically in the range of 10^2–10^6 photons/s. Although these signals are relatively weak, they are easily detectable with photomultiplier tubes (PMT) and appropriate electronics.

The basic arrangement for surface SHG measurements is shown in Figure 5. It makes use of the directionality and frequency selectivity of the SHG process not only to detect the desired signal with high efficiency, but to discriminate strongly against background signals, including the reflected laser beam. In the setup, irradiation of the sample involves a pulsed laser source, LS; a halfwave plate, λ, and polarizer, P, for controlling the input polarization. Spectral control is achieved with a filter F1 that passes the fundamental radiation in the pump beam, but rejects other wavelengths, particularly spurious SH radiation arising from other optical components; and a color filter F2 that passes SH, but rejects the reflected fundamental radiation. In addition, a spectrometer is commonly employed to limit the detection bandwidth further. An analyzer A serves to select the desired SH polarization. The SH signal is then measured by a high-quantum efficiency detector and the signal is monitored by processing electronics, typically a photon counter, a gated integrator, or a lock-in amplifier, depending on the strength of the signal and the repetition rate of the laser. The laser source may be either of fixed wavelength or tunable for spectroscopic measurements.

There are other important experimental configurations for surface SHG that extend beyond the basic SH reflection geometry, shown schematically in Figure 6a. A common improvement (Figure 6b) is the implementation of a SH reference in which a small fraction of the pump radiation is directed into a crystal with a bulk second-order nonlinear response. This approach provides a reference against which to compare the measured signal, thus compensating appropriately for pulse-to-pulse variation in duration,

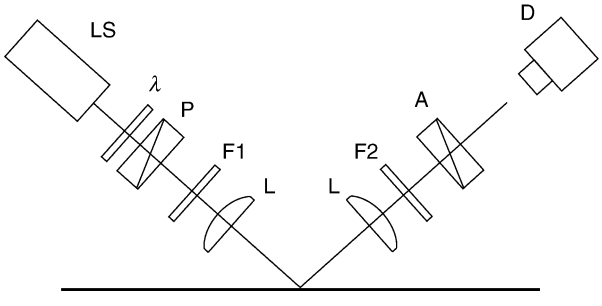

Figure 5 Schematic representation of a basic surface experimental setup for surface SHG. It is comprised of laser source (LS), halfwave plate (λ), polarizer (P), lenses (L), spectral filters (F1, F2), analyzer (A), and detector (D).

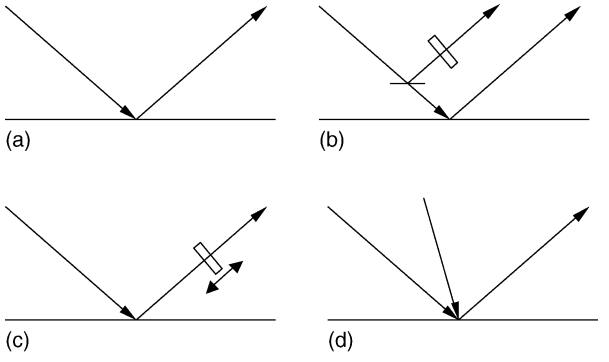

Figure 6 Various schematic representations of different experimental schemes for surface SH measurements. Panel (a) represents the basic scheme as in Figure 5. Panel (b) describes use of a separate SH source as a reference for normalizing the surface SH signals against laser fluctuation and drift. Panel (c) represents the arrangement for a measurement of the phase of the surface SH signal by mixing the fields from the surface and an external source SH radiation. Panel (d) describes the configuration for a time-resolved measurement using the pump-probe scheme.

energy, and spatial profile, as well as for long-term drifts. This type of normalization (against a material with a suitably flat spectral response) is essential for spectroscopy measurements in which the laser frequency is scanned. In addition, use of a calibrated reference is the best way of determining the surface nonlinear response in absolute terms.

It may also be desirable to measure the phase of the signal. For this type of an experiment, a reference field, $\mathbf{E}_{\text{ref}}(2\omega)$, of similar amplitude and known phase response is generated along the path of the surface SH signal $\mathbf{E}(2\omega)$ (Figure 6c). The two collinear SH beams of the same polarization interfere at the detector. The SH power scales as $|\mathbf{E}_{\text{ref}}(2\omega) + \mathbf{E}(2\omega)|^2 = |\mathbf{E}_{\text{ref}}|^2 + 2E_{\text{ref}}E\cos\varphi + |\mathbf{E}|^2$, where φ is the relative phase of the two fields. The relative phase φ may be varied by translating a reference plate along the path of the beam and making use of the dispersion of the ambient air or by inserting another control phase-shifting element. A variant of this phase measurement method is the homodyne scheme in which the reference electric field amplitude $\mathbf{E}_{\text{ref}}(2\omega)$ is significantly stronger than that of the signal amplitude $\mathbf{E}(2\omega)$. The measured SH power then scales as $|\mathbf{E}_{\text{ref}}|^2 + 2E_{\text{ref}}E\cos\varphi$, which yields a signal that varies linearly with the desired SH field strength from the sample.

In the SHG technique, a short-pulse laser is used to interrogate the sample and thus the measurement provides high time-resolution. To make use of this capability, we can add a pump pulse to excite the sample away from equilibrium. This provides the opportunity to examine ultrafast surface dynamics induced by excitation of the sample with a suitable pump laser pulse. For such measurements (Figure 6d), the pump pulse is generally derived from the same laser source as the probe for the SHG measurement, although one or both of these pulses may undergo frequency conversion before being applied to the surface. The critical element is that time synchronism is maintained. The dynamics can then be followed by repeating the SHG measurement at various time delays relative to pump excitation, as controlled by an optical delay line. The ultimate time resolution of this technique is limited only by the duration of the laser pulses and may be as short as a few femtoseconds with state-of-the-art modelocked lasers.

Applications of Surface SHG

The technique of surface SHG is extremely flexible in application, since it relies only on basic symmetry properties for its remarkable surface or interface specificity. SHG measurements can provide quite varied information about the interface, depending on the mode of application of the technique and the material system under study. In this section, we attempt to illustrate the principal types of measurements that can be performed with SHG and the information that can be obtained thereby. For systems with molecular adsorbates, SHG studies can yield information on the density and orientation of molecular species, and can typically do so in real time. For crystalline surfaces, the symmetry and order of the surface can be examined through studies of tensor properties of the surface nonlinear susceptibility. Spectroscopic studies of electronic transitions are also of great value. These can be accomplished for both solids and molecular systems through the same experimental approach of tuning the frequency of the laser source. In all of these investigations, one can achieve very high time resolution, down into the femtosecond range, by the use of pump-probe techniques. In addition, as we discuss below, SHG provides interesting additional capabilities for systems with applied electric and magnetic fields. Finally, the method permits one to probe spatially inhomogeneous systems.

In addition to this diverse range of information that can be provided by surface SHG measurements, the technique is unique in the extremely wide range of material and chemical systems to which it can be – and, indeed, has been – applied. These span the gamut from solids under ultrahigh vacuum to solid/solid, solid/liquid, liquid/vapor, and even liquid/liquid interfaces. Since our examples were drawn to illustrate the type of information obtainable, rather than the range of material systems investigated, the reader is unfortunately obliged to refer to other more detailed treatments of surface SHG measurements to appreciate fully this important facet of the technique.

Adsorbate Density

The remarkably high sensitivity of the SHG technique to the nature of the surface is illustrated by the data in Figure 7, which shows the dramatic change in the SH response from a clean Si(111)-7 × 7 surface upon adsorption of atomic hydrogen. Indeed, it is possible to detect well below 1% of a monolayer (ML) of adsorbed hydrogen. A useful point to note is that the change in $\chi_s^{(2)}$ is linear with adsorbate density for modest values of the coverage, θ. Thus, it is quite easy to obtain a relative gauge of the adsorbate coverage in this regime.

The behavior of the SH response to adsorbates at low coverages can often be described by a simple linearized model of the surface nonlinear susceptibility of $\chi_s^{(2)} = (1 - a\theta)\chi_{s,1}^{(2)} + \theta\chi_{s,2}^{(2)}$, where

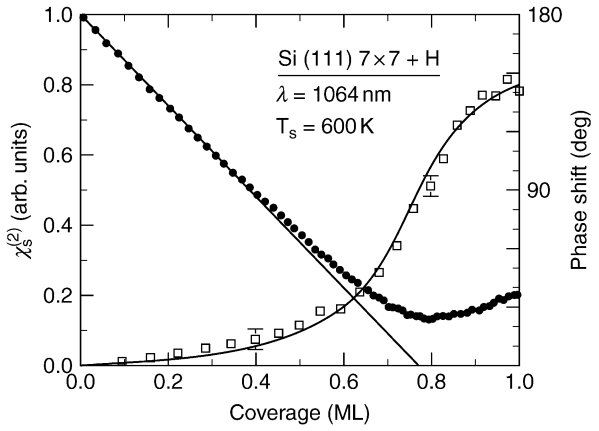

Figure 7 Dependence of the magnitude (full circles) and the phase (open squares) of the nonlinear susceptibility $\chi_s^{(2)}$ for a Si(111)-7 × 7 surface as a function of the coverage of adsorbed atomic hydrogen using a fundamental photon energy 1.17 eV. Reproduced with permission from Höfer U (1996) Nonlinear optical investigations of the dynamics of hydrogen interaction with silicon surfaces. *Applied Physics A* 63: 533.

$\chi_{s,i}^{(2)}$ $(i = 1, 2)$ are complex quantities and a is a constant. This relation describes the surface nonlinear susceptibility as arising from a contribution $\chi_{s,1}^{(2)}$ from the clean surface and a contribution $\chi_{s,2}^{(2)}$ from a saturated monolayer $(\theta = 1)$ of the adsorbate. The term $-a\theta\chi_{s,1}^{(2)}$ then represents the modification of the surface nonlinearity arising from interaction with the adsorbate. For the case of hydrogen adsorption of Figure 7, this is the dominant term, since hydrogen atoms would have no nonlinearity on their own. In other systems, however, the response can be considered as arising essentially from the nonlinear response of aligned adsorbed molecules. The simple linearity of this relation of $\chi_s^{(2)}$ with adsorbate coverage obviously neglects important effects such as adsorbate–adsorbate chemical interactions, as well as local-field effects and the possible influence of differing adsorption sites. All of these factors have been considered in the literature. Nonetheless, the linearity of response with adsorbate coverage is often found to be a good approximation, even for fairly high adsorbate coverages. From the point of view of simply following adsorption dynamics with SHG, it is not, we note, necessary to have any a priori knowledge of the relation between the adsorbate coverage and the SH response. This relation can be established empirically in static measurements and then used advantageously to follow the dynamics of surface processes.

Surface Symmetry and Molecular Orientation

The surface SHG process is described by the third-rank tensor $\boldsymbol{\chi}_s^{(2)}$. The tensorial properties of this response reflect the symmetry of the surface. Other than for a few cases of high symmetry, such a third-rank tensor gives a distinct signature of surfaces with crystalline order compared to surfaces, such as disordered ones, exhibiting effective in-plane isotropy. The form of the $\boldsymbol{\chi}_s^{(2)}$ tensor can be probed both by measurements that vary the polarization of the fundamental and second-harmonic beams and by measurements in which the plane of incidence is changed with respect to the orientation of the surface, generally by rotating the sample about its normal with a fixed experimental geometry.

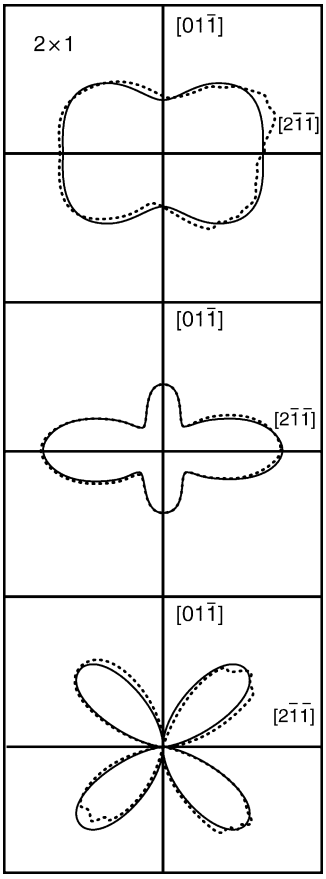

Figure 8 Polarization dependence of SHG for normal incidence excitation of the cleaved Si(111)-2 × 1 surface. The polar plot of the SH signal versus the pump polarization orientation is shown for the case of no polarization analysis (top panel), for the SH analyzer along the [2$\bar{1}\bar{1}$] crystallographic direction of the surface (middle panel), and along the [01$\bar{1}$] direction (bottom panel). The solid curves are fits to theory assuming that the surface has *m* symmetry. Reproduced with permission from Heinz TF, Log MMT and Thomson WA (1985) Study of Si(111) surfaces by optical second-harmonic generation: reconstruction and surface phase-transformation. *Physical Review Letters* 54: 63.

Figure 8 illustrates the capability of surface SHG measurements to probe surface symmetry. The figure shows SHG polarization dependence for a Si(111) surface cleaved in ultrahigh vacuum. While the

underlying bulk symmetry suggests that the surface might exhibit 3m symmetry, the analysis of data indicates that only a single mirror m plane is present. This lowered symmetry corresponds to the metastable 2×1 reconstruction induced by the crystal cleavage. By heating the sample, one can observe a phase transformation to the equilibrium 7×7 reconstruction and the emergence of the corresponding 3m surface symmetry.

The analysis of surface or interface symmetry by SHG relies only on the form of the nonlinear susceptibility tensor, i.e., which elements are independent and nonvanishing. Within the context of a microscopic model of the surface response, however, the relative values of the tensor elements of $\boldsymbol{\chi}_s^{(2)}$ can also yield valuable information about the nature of the surface. This approach has been developed extensively in the context of the analysis of molecular orientation at surfaces. The basic notion behind this treatment relies on the knowledge of the microscopic molecular nonlinear polarizability $\alpha^{(2)}_{\lambda\mu\nu}$ and the measured surface nonlinear susceptibility $\chi^{(2)}_{s,ijk}$ to infer information about the orientational average that relates these quantities. As discussed above in conjunction with eqn [10], under the neglect of local-field corrections, the relationship between these two quantities involves the ensemble average of the coordinate transformation tensor from the molecular to the laboratory coordinate systems $\langle T_{i\lambda} T_{j\mu} T_{k\nu} \rangle$. Hence a knowledge of the quantities $\alpha^{(2)}_{\lambda\mu\nu}$, N_s, and $\chi^{(2)}_{s,ijk}$ allows us to infer information about the orientational distribution of the molecules as described by the quantity $\langle T_{i\lambda} T_{j\mu} T_{k\nu} \rangle$. Even in the absence of knowledge of the magnitudes of the nonlinear polarizabilities and the adsorbate density, one may still obtain useful information for molecules with a simple form of $\alpha^{(2)}_{\lambda\mu\nu}$.

An important example of this analysis of molecular orientation concerns the case of molecules with a dominant nonlinear polarizability along a single axis, i.e., $\boldsymbol{\alpha}^{(2)} = \alpha^{(2)}_{z'z'z'} \hat{\mathbf{z}}' \hat{\mathbf{z}}' \hat{\mathbf{z}}'$. For the usual situation of in-plane isotropy, one can then show that the nonlinear susceptibility elements are given by $\chi^{(2)}_{s,\perp\perp\perp} = N_s \langle \cos^3\theta \rangle \alpha^{(2)}_{z'z'z'}/\varepsilon_0$ and $\chi^{(2)}_{s,\parallel\perp\parallel} = \chi^{(2)}_{s,\parallel\parallel\perp} = \frac{1}{2} N_s \langle \cos\theta \times \sin^2\theta \rangle \ \alpha^{(2)}_{z'z'z'}/\varepsilon_0$, where θ denotes the angle between the surface normal and the z' molecular axis. It should be noted that these orientational moments, reflecting their origin in a third-rank tensor, give a signature of the polar ordering, since a sign change in the elements of $\boldsymbol{\chi}_s^{(2)}$ follows if the molecular orientation is inverted. Also, when only one element of $\boldsymbol{\alpha}^{(2)}$ is present, we can form ratios of the experimentally measurable ratio of tensor elements that depend only on the molecular orientational factors, such as $R \equiv (2\chi^{(2)}_{s,\parallel\perp\parallel} + \chi^{(2)}_{s,\perp\perp\perp})/\chi^{(2)}_{s,\perp\perp\perp} = \langle \cos\theta \rangle / \langle \cos^3\theta \rangle$. For a narrow distribution of the orientations centered at θ_0, this ratio yields directly the molecular orientation angle through $R \approx \sec^2\theta_0$.

This type of molecular orientation analysis has been applied to a wide range of material systems. The method, while powerful, relies on several assumptions, including an adequate knowledge of the molecular nonlinear polarizability, the lack of significant local field corrections, the availability of information about the effective linear dielectric constant in the interfacial region, and a suitable method of eliminating any substrate nonlinear response in the measurement. The method is, consequently, best suited for adsorbed layer of molecules with strong and well-defined nonlinear response, present at relatively modest coverages. The use of resonant excitation is a valuable adjunct in these studies, since it generally simplifies the form and strengthens the molecular nonlinear response. An analogous approach to the analysis of molecular orientation can be accomplished with infrared–visible sum-frequency generation. These measurements often provide a superior method of analysis, since the molecular response and its symmetry are better defined by resonant excitation of a molecular vibration.

Surface and Interface Spectroscopy

Surface SHG can be readily adapted to yield spectroscopic information on surface transitions. As indicated above, both resonances at the fundamental and second-harmonic frequencies are manifested in the SHG response. The examination of resonances at the SH frequency is often convenient, since it permits the application of a relatively intense pump radiation at a frequency well separated from that of the resonance. Such SHG spectroscopy measurements have been widely applied to examine electronic transitions at surfaces and interfaces of solids, as well as in adsorbed molecules under a wide variety of conditions.

An example of SHG spectroscopy of electronic transitions at a buried solid/solid interface is presented in Figure 9. For the epitaxial CaF_2/Si(111) interface, distinctive new electronic transitions, associated with interface states, are observed that are absent from the response of either of the bulk materials. These excitations occur in a spectral range where the bulk silicon sample is highly absorbing, which would render the identification of the new interface transitions very difficult using conventional linear optics. The buried nature of the interface naturally also constrains application of conventional surface probing techniques involving electron

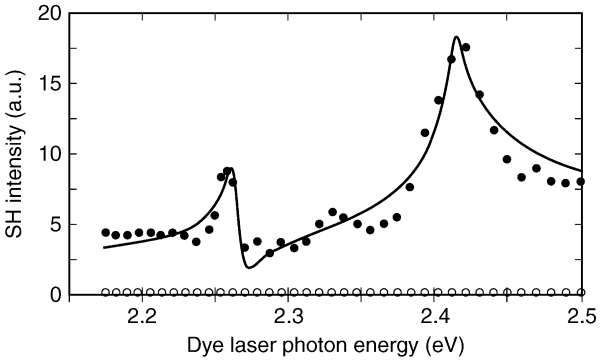

Figure 9 SHG spectrum (solid dots) for the CaF_2/Si(111) interface. For comparison, the open circles represent the corresponding signals for the SiO_2/Si(111) interface, which is seen to give a very weak signal in this frequency range. The solid line is a theoretical fit based on a two-dimensional direct transition of the interface states, together with an excitonic feature slightly below the band gap. Figure 10 Rotational relaxation of Coumarin 314 molecules at the air–water interface subsequent to photoexcitation. The initial anisotropy in the molecular orientational distribution is created by linearly polarized pump radiation in two orthogonal directions in the surface. Reproduced with permission from Zimdars D, Dadap JI, Eilsenthal KB and Heinz TF (1999) Anisotropic orientational motion of molecular adsorbates at the air–water interface. *Journal of Physical Chemistry B* 103: 3425–3433.

irradiation or emission. Two additional general observations are appropriate. First, the lineshape analysis for such measurements must take into account the fact that the SHG response derives from both the real and imaginary parts of $\boldsymbol{\chi}_s^{(2)}$, as we discussed above. Second, in the absence of any other knowledge, SHG spectroscopic data contain an ambiguity about whether the resonances correspond to the fundamental or SH photon energy. This ambiguity, however, can be resolved in a straightforward fashion by complementing the SHG measurement with a sum-frequency measurement in which one frequency is scanned and one is held fixed, as was demonstrated in the study associated with Figure 9.

Time-Resolved Measurements

One of the fascinating frontiers that can be addressed by SHG measurements is probing the ultrafast dynamics of surfaces and interfaces by the pump-probe method. This possibility is exemplified by a variety of studies ranging from the dynamics of laser-driven phase transitions, charge-transfer, solvation, phonon dynamics, and orientational and torsional dynamics.

An example of applying time-resolved SHG to examine ultrafast molecular dynamics at the liquid/vapor interface of water is presented in Figure 10. In these studies, the rotational motion of dye molecules at the interface, which probes the local environment, is followed in real time. This is accomplished by photo-exciting the dye molecules at the interface. Because polarized pump radiation is used, an anisotropic orientational distribution of excited-state molecules is established. Since the excited molecules have a different SHG response, a change in the signal is observed immediately. Subsequently, the anisotropic orientational distribution relaxes to the equilibrium configuration. The time evolution of the rotational anisotropy is followed by detecting the SH of a probe laser pulse as a function of the delay time. Through a comparison of the results for different initial anisotropic distributions (produced by pump beams with differing polarizations), one may deduce rates for both in-plane and out-of-plane orientational relaxation. This example illustrates the possibilities of time-resolved SHG measurements for probing the detailed dynamics of molecules at an interface on the ultrafast timescale.

Spatially Resolved Measurements

Up to this point, our discussions have centered on spatially homogenous surfaces and interfaces. Surface SHG has also been exploited to probe the lateral variation of inhomogeneous surfaces with the micron to sub-micron resolution characteristic of optical microscopy techniques. Spatial resolution may be achieved simply by detecting the nonlinear response with a focused laser beam that is scanned across the surface. A large area of the surface may also be illuminated and the emitted nonlinear radiation imaged. A wide range of applications of this imaging capability has emerged, including the probing of biological materials, such as cells and tissues, to probing spatially varying electric fields

and magnetic domains. Within the biological context, SH microscopy has recently become an active research direction. In these applications, while probing with SHG typically senses non-centrosymmetric structures in bulk samples as opposed to interfaces, most of the aspects of SHG presented in this article still apply. To further improve the spatial resolution of SHG microscopy, researchers have also employed near-field techniques for spatial resolutions below the diffraction limit.

Complementary approaches to the real-space imaging just described have also been developed based on SH diffraction. In this scheme, periodically modulated surfaces are established holographically on a surface by utilizing two interfering laser beams. In addition to the reflected and transmitted SH beams, additional beams are then generated at well-defined angles as dictated by the grating period. This approach has been used to monitor the relaxation of a monolayer grating of adsorbates in time, which yields precise information on the rate of adsorbate surface diffusion.

Probing Electric Fields at Interfaces

For centrosymmetric media, the SHG process shows a high degree of sensitivity to the presence of electric fields. This property follows from the fact that an applied electric field can break the inversion symmetry, just as an interface does. The resulting process, termed electric-field induced SHG (or EFISH), has been known for many years. From a phenomenological standpoint, it can usually be described as a nonlinear response of the form $\mathbf{P}^{(3)}(2\omega) = \varepsilon_0 \boldsymbol{\chi}^{(3)} : \mathbf{E}(\omega)\mathbf{E}(\omega)\mathbf{E}$, where $\mathbf{E}$ is the electric field being probed and $\mathbf{E}(\omega)$ is the laser pump field. Within the context of surfaces and interfaces, there are many circumstances where probing such electric fields is of interest and importance. The SHG technique provides high sensitivity, good spatial resolution, accessibility to buried interfaces, and, in the pump-probe implementation, extremely high time resolution. In addition, with appropriate measurements of the polarization dependence and homodyne detection, the full vector character of the electric field can be determined.

The behavior of electric-field induced SHG is similar to that arising from the asymmetry of an interface. Indeed, it is formally equivalent to the response of an interface provided that the electric field is present in (or radiates from) a region of less than a wavelength's thickness. The applications of this measurement capability are quite diverse, ranging from studies of charging and acid/base reactions at liquid/solid interfaces to probing fields in metal-oxide-semiconductor structures and Schottky barriers to the measurement of freely-propagating terahertz radiation. In Figure 11,

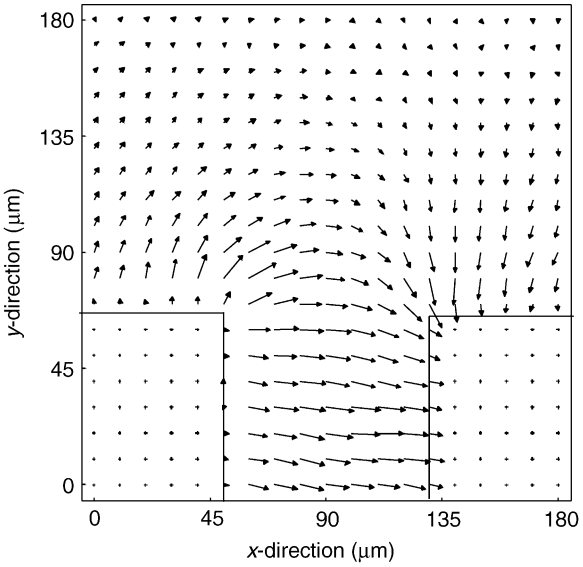

Figure 11 Vector map of the electric field in Si-on-sapphire substrate as deduced by SHG measurements. A voltage is imposed on the rectangular metallic electrodes, which are separated by 80 μm. Reproduced with permission from Dadap JI, Shan J, Weling AS, Misewich JA, Nahata A and Heinz TF (1999) Measurement of the vector character of electric fields by optical second-harmonic generation. *Optics Letters* 24: 1059–1061.

SHG with appropriate polarization control and homodyne detection scheme has been applied to the measurement of the vector character of electric fields present in a dc-biased dipole structure on silicon. By spatially scanning the laser beam, a two-dimensional electric field map can be produced. In a pump/probe scheme, the same measurements can be made with femtosecond time resolution.

Probing Magnetization at Interfaces

In contrast to the application of an external electric field (a polar vector), the presence of an external magnetic field (an axial vector) does not break the inversion symmetry of a material. Thus, SHG retains its interface selectivity for magnetic effects. SHG measurements, as an interface-specific probe, thus provide an excellent complement to the linear magneto-optical Kerr effect (MOKE), which is sensitive to magnetic effects within the penetration depth of the light.

The ability of the SHG technique to sense the magnetization at a surface is illustrated in Figure 12 for a film of epitaxially-grown magnetic Co on nonmagnetic substrate Cu. A hysteresis loop of the magnetization versus the strength of an applied magnetic field is shown, where the magnetization is gauged from the SHG response. Through measurements of the response as a function of the thickness of

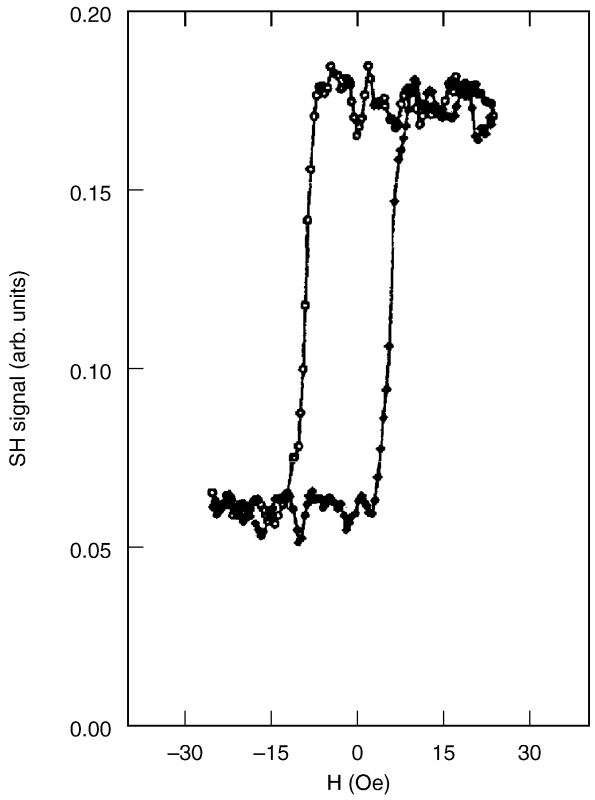

Figure 12 SH response of a Co film on a Cu(001) substrate as a function of the applied magnetic field. A hysteresis loop corresponding to the surface response is observed. Reproduced with permission from Wierenga HA, de Jong W, Prins MWJ *et al.* (1995) Interface magnetism and possible quantum-well oscillations in ultrathin Co/Cu films observed by magnetization induced second harmonic generation. *Physical Review Letters* 74: 1462–1465.

the magnetic film, the researchers demonstrated that the SH response reflected the interface properties, rather than those of the bulk film.

Probing Micro- and Nanoscale Structures

In addition to the microscopy studies described above that probe spatially inhomogeneous surfaces, there has been considerable interest in SHG from a variety of strongly textured surfaces and small particles. From the standpoint of the optical response of materials, particular interest has been attached to studies of metallic surfaces with surface roughness. For appropriate roughness of low-loss materials, such as silver, very significant local-field enhancements can be achieved. Since these field enhancements enter into the strength of the SH emission nonlinearly, overall enhancements in the SH power by several orders of magnitude have been demonstrated. This provides both a useful method of study of such surface enhancement effects and a scheme for amplifying the relatively weak surface nonlinear response.

Beyond these problems associated with roughened surfaces, considerable attention has recently been directed towards the application of the SHG technique for probing micro- and nano-scale particles. The fundamental principle of the interface selectivity of the SHG process for such systems comprised of centrosymmetric materials remains unaltered. The interaction of these particles with the radiation fields is, however, significantly modified. For the case of particles with dimensions of several optical wavelengths, the overall SHG signal strength may be comparable to that from a corresponding area of a planar surface. The radiation pattern will, of course, be strongly modified and will generally be diffuse in character. While this makes detection (and background discrimination) somewhat more difficult than for the planar geometry, many SHG measurements of surface and interface properties have been carried out in this regime. As the particle size becomes progressively smaller, particles with overall inversion symmetry begin to exhibit appreciable cancellation of the SH emission. Indeed, in the limit of vanishing size, full cancellation is expected. This tendency is, however, offset by the increasing surface-to-bulk ratio and the possibility of increasing the number of particles probed. It has been demonstrated experimentally that the surfaces of particles in the nanometer length scale can indeed be probed by SHG.

From the point of view of applications, this extension of the SHG technique to probe micro- and nano-structured materials opens up a rich variety of new possibilities. Results have been reported on metal and semiconductor nanoparticles in suspension, as well as on colloids of minerals. In addition, liquid droplets have been investigated. Self-assembling structures such as liposomes and vesicles have been examined. For these structures, many of the same capabilities of SHG as demonstrated for the planar geometry, such as probing of adsorption and charging effects, have been demonstrated. More uniquely, molecular transport *through* the liposome membrane could also be observed and characterized. The possibility of extension of these measurements to biological systems is of obvious interest and promise.

Concluding Remarks

In this article, we provided a brief review of surface SHG as a technique for interface-specific probing of materials. In addition to discussing some of the fundamental ideas underlying the method, we outlined the wide variety of information that may be obtained from such measurements, ranging from

surface symmetry and molecular ordering to interface spectroscopy and ultrafast dynamics. While several aspects of the method have now become quite well established, developments in widely available modelocked lasers with excellent performance characteristics have greatly enhanced the ease of making surface SHG measurements in a wide class of material systems. In addition, new developments and applications of the method have continued to emerge apace. Of particular note in this regard are applications to probe electric fields and magnetization at interfaces, as well as advances in the use of the method for interface-specific probing of micro- and nanoscale structures. The sharp increase in applications of SHG for probing systems of biological importance constitutes another important development, and one with much promise for the future.

Single Molecule Spectroscopy

X Michalet and S Weiss, University of California, Los Angeles, CA, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Textbooks in physics, chemistry, and biology abound in diagrams depicting single-particle, single-molecule or single-enzyme properties, reactions or interactions with their environment. Such pictures and the numbers associated with them, however, were, until recently, extrapolated from measurements performed on large ensembles of molecules, which only yield quantities averaged out over time, space, conformations and/or the local environment. Advances in detector sensitivity and improvements in instrument design do now provide scientists

with tools to probe single molecules with light, and monitor their photophysical properties with exquisite sensitivity and time resolution. This spectroscopic information is used to explore the molecular structure, conformational dynamics, local environment, and intermolecular interactions. The collected data generate a wealth of new information on single-molecule physical chemistry or biomechanics, but also in polymer gel physics or glass dynamics and other domains of solid state physics.

This article reviews the field of single-molecule spectroscopy. First, the principles underlying single-molecule spectroscopy approaches are introduced, and this is followed by a discussion of the different spectroscopic techniques available to the experimentalist and what kind of information can be extracted with each of them. It also discusses important photophysical properties of molecules that influence the outcome of single-molecule spectroscopic measurements. The next section presents some applications of these techniques, focusing on physical properties of materials and biological applications of single-molecule spectroscopy. The last part briefly reviews recent developments and outlines the future prospects of single-molecule spectroscopy.

Principles of Single-Molecule Spectroscopy

Motivation

Measurements performed on ensembles of molecules only yield averaged-out information. This averaging process is of several kinds: average over molecular heterogeneity (e.g., chemical composition, oxidation state, or spatial conformation) and average over different or changing local environments. Moreover, dynamic processes studied by ensemble measurements cannot sort out molecules exhibiting fast or slow reaction times, although such differences are expected from the stochastic nature of any chemical kinetics. The interest in single-molecule analysis is for these reasons manifold. At low temperature, being able to study a single molecule and its evolution under the influence of various external parameters allows for precise tests of molecular quantum electrodynamics. At higher temperature, it gives access to the temporal evolution of different nanodomains of a bulk material in which single molecules are embedded as reporters of their environment. In biology and biochemistry, the building blocks of any process are individual molecules (genes, enzymes, motors, filaments, etc.); the ability to fully understand their kinetic behavior at the single-molecule level is thus of utmost importance. Finally, reliable observation of single molecules is a prerequisite of the full development of nanotechnology and quantum computing.

Historical Outlook

Single-molecule experiments were first performed on isolated ion channels by the patch clamp technique, which allows the recording of single-ion translocation through a pore-like protein embedded in a fluid membrane. Scanning tunneling and atomic force microscope observations later opened the way to investigations of nanometer-scale objects on surfaces. Only recently have optical methods reached the sensitivity required to detect, image, manipulate, and follow the spectroscopic evolution of single molecules on surfaces, in solids, liquids, and biological membranes as well as inside live cells.

Single-molecule spectroscopy (SMS) was initially demonstrated in a system of pentacene molecules embedded in a *p*-terphenyl host crystal at liquid helium temperature. Absorption (leading to fluorescence excitation) spectroscopy in this system takes advantage of the very narrow zero-phonon absorption line (ZPL) of the rigid pentacene molecule (Figure 1). The position in laser-frequency space of each molecule's ZPL indeed depends on the local fields, allowing for precise molecular selectivity. However this approach is limited to a few molecule–host pairs and requires cryogenic techniques, due to broadening of the ZPL above 10 K.

Room temperature studies started with total internal reflection (TIR) microscopy and standard flow-cytometry methods in the mid-1980s. In the latter case, single molecules randomly passing through the excitation volume gave rise to sudden bursts of photons emitted during their brief transit. Initially developed for rapid DNA sequencing, this simple approach is now widely used for more sophisticated studies in its confocal version (Figure 2), which will be detailed in the following.

The first image of a single molecule at room temperature was later obtained using scanning near-field optical microscopy (Figure 3), rapidly followed by similar achievements using far-field confocal microscopy, at the expense of a lower spatial resolution, but with much more ease of use. TIR and wide-field fluorescence imaging are now used to image and study the two-dimensional and three-dimensional diffusion trajectories of single fluorescent molecules (Figure 4), making a come-back after the pioneering studies of the early 1980s.

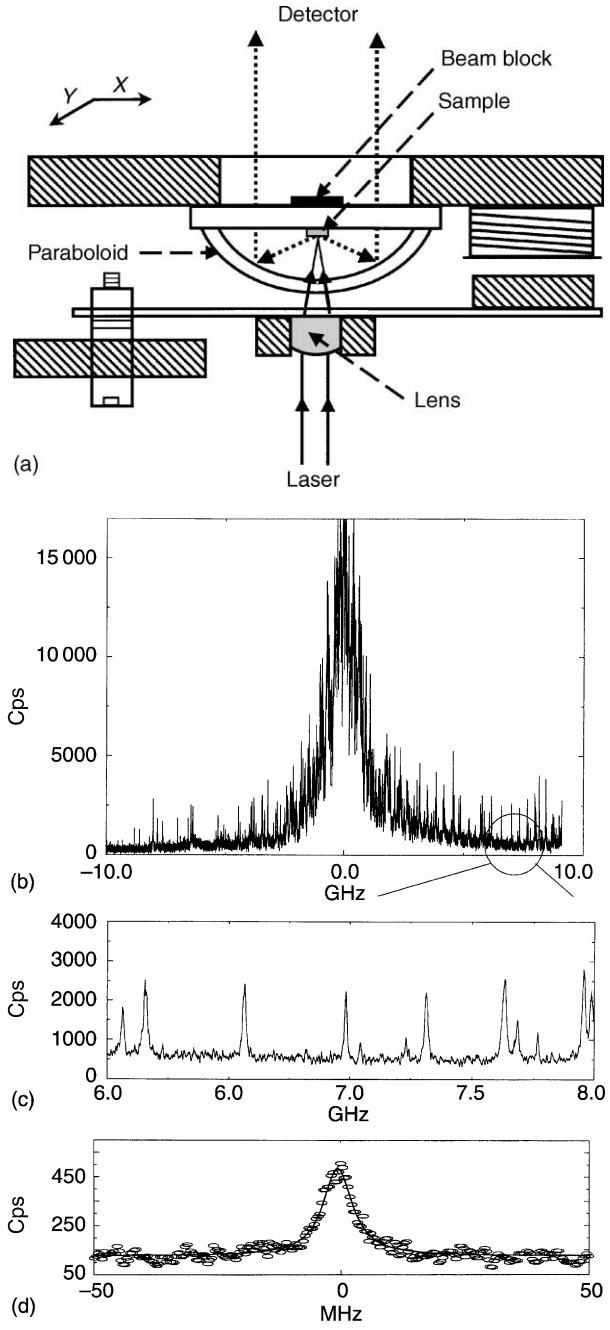

Figure 1 Fluorescence excitation spectra of pentacene in *p*-terphenyl at 1.5 K. (a) Schematic of the cryogenic setup used. A laser beam is focused onto the sample through a lens into the cryogenic chamber. The sample can be moved in the *XY* plane, with a magnet and coil pair. A beam block rejects the incident laser light (black arrow). A paraboloidal mirror collects the emitted fluorescence (dashed arrows) and redirects it towards the detector (photomultiplier tube). The laser frequency (linewidth 3 MHz) is tuned around the absorption line center at 592.321 nm. (b) Broad scan showing the inhomogeneously broadened line shape of pentacene molecules embedded in a *p*-terphenyl crystal at 1.5 K. The sharp lines correspond to spectra of individual molecules (see panel c) (cps: counts per second). (c) Detail of the previous spectrum showing spectra of several individual molecules. The variability of intensities is due to the different positions of the molecule in the excitation beam. (d) Individual molecule spectrum obtained at lower excitation power exhibiting a Lorentzian shape (solid line) centered at 592.407 nm with a lifetime-limited width of 7.8 MHz (intensity is measured in counts-per-second for all three spectra). (a): adapted from Ambrose WP, Basché T and Moerner WE (1991) Detection and spectroscopy of single pentacene molecules in a *p*-terphenyl crystal by means of fluorescence excitation. *Journal of Chemical Physics* 95: 7150–7163. (b)–(d): after Moerner WE (1994) Examined nanoenvironments in solids on the scale of a single, isolated impurity molecule. *Science* 265: 46–53. Requirements for Single-Molecule Sensitivity

Observing single molecules may be as easy as finding a needle in a haystack if background, signal and noise are not carefully optimized. Simple considerations illustrated in Figure 5a help measure the technical challenge bearing on single-molecule optical detection. Whatever the type of detected signal (fluorescence, Raman scattering, or others), it is characterized by an absorption cross-section σ (probability of photon absorption) and a quantum yield Q (number of emitted photons per absorbed photon). The optical setup transmits an excitation power P at a frequency ν, resulting in a signal rate $s = EQ\sigma P/(Ah\nu)$ expressed in counts per second (or Hz). This rate is proportional to P/A where A is the cross-section of the excitation beam in the plane of the molecule. E is the collection efficiency of the setup. The environment adds a background rate b per unit volume and unit power, and the detector contributes a dark count rate D. Neglecting noise from the readout electronics, a measurement of duration τ will yield the following signal-to-noise ratio (SNR):

$$\mathrm{SNR} = \frac{s\tau}{\sqrt{(s + bVP + D)\tau}} \qquad [1]$$

where V is the excited volume. The denominator is the root mean square of all contributions to the measured count rate, considered shot-noise limited. The SNR obviously increases at larger integration time τ. Another important quantity is the signal-to-background ratio (SBR):

$$\mathrm{SBR} = \frac{EQ\sigma}{bVAh\nu} \qquad [2]$$

These ratios can be increased by improving the collection efficiency E or decreasing the excitation volume V. A larger excitation power or a longer integration time will improve the SNR without affecting the SBR. Typical values for the above

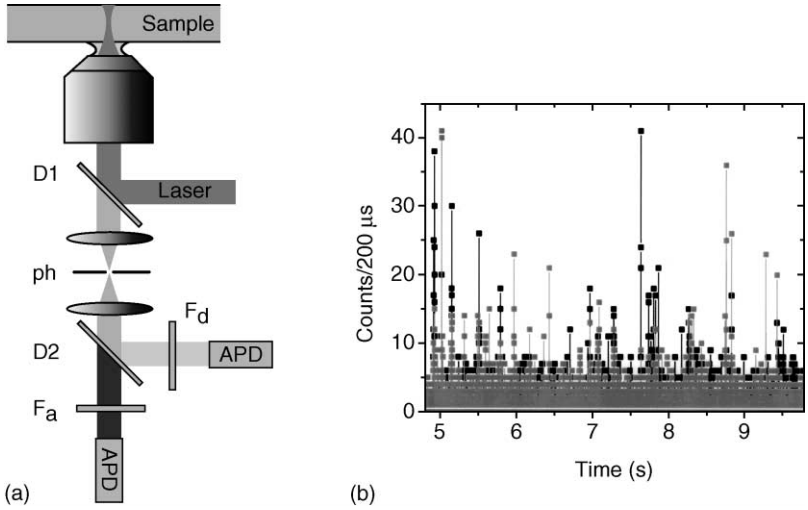

Figure 2 Single-molecule fluorescence burst detection. (a) Schematic of the confocal setup used for single-molecule fluorescence detection. A collimated laser beam is focused through a high numerical aperture (NA) objective in a liquid cell. Molecules diffusing through the diffraction-limited excitation volume (~1 fl) emit photons during their passage, which are collected by the same objective. A dichroic mirror (D1) separates excitation and emission wavelengths. The emitted light is focused on a pinhole (ph) in order to reject out-of-focus background light, and finally recollimated onto two different avalanche photodiodes (APDs) after spectral separation by a dichroic mirror (D2). Filters specific for each channel (F_a: acceptor channel, F_d: donor channel) may be used to improve spectral separation. (b) 5 s time trace of recorded bursts for a 30 pM solution of doubly labeled DNA in 20 mM sodium phosphate buffer. The DNA constructs are used for distance measurement (detailed in **Figure 9**) and have a TMR fluorophore attached to one end of the DNA molecule and a CY5 fluorophore attached to the *n*th base from the end. The time traces correspond to $n = 12$. Gray: TMR fluorescence (donor); black: CY5 fluorescence (acceptor). The laser excitation (0.6 mW, 514 nm) is focused 10 μm within the solution through an oil immersion objective (numerical aperture: 1.4). For each detected photon, the APD generates a pulse, which is recorded by a computer-embedded acquisition board. Counting these events into 200 μs bins, the resulting time trace exhibits distinct bursts distributed randomly in time, with duration and amplitude corresponding to a Brownian diffusion of individual molecules through the excitation volume. (b): is adapted from Deniz AA, Dahan M, Grunwell JR, *et al.* (1999) Single-pair fluorescence resonance energy transfer on freely diffusing molecules: Observation of Förster distance dependence and subpopulations. *Proceedings of the National Academy Sciences USA* 96: 3670–3675. Figure 3 Scanning near-field imaging of single molecules at room temperature. (a) Schematic of a scanning near-field optical microscope setup used for single-molecule imaging. An aluminum-coated tapered optical fiber (raster-scanned at nanometer distance from the sample) serves as a waveguide for laser excitation. Shear-force feedback keeps the tip at a constant distance from the sample, resulting in a signal used for nanometer-resolution topographic reconstruction of the scanned area. The excitation volume and the corresponding local evanescent electric field are detailed in the expanded view. Fluorescence light emitted by individual molecules is collected by an oil immersion, high NA objective and recorded by an avalanche photodiode. (b) $4 \times 4\ \mu m^2$ area of a polymethylmethacrylate (PMMA) coated coverslip on which a diluted methanol solution of a lipophilic carbocyanine dye, $diIC_{12}$, has been deposited. Scanning was performed with randomly polarized light. (c) Orientation of the corresponding individual emitting dipole determined by modeling the field distribution (expanded view in a), simulation of the absorption intensity with polarized excitation and comparison with data obtained at two different excitation polarizations. (a): Adapted and (b), (c) reprinted with permission from Betzig E and Chichester RJ (1993) Single molecules observed by near-field scanning optical microscopy. *Science* 262: 1422–1425. Figure 4 Single molecule diffusion in two dimensions. (a) $6.8 \times 6.8\ \mu m^2$ images of fluorescently labeled lipids (tetramethylrhodamineinthiocarbamoyl, linked to 1,2-dihexadecanoyl-*sn*-glycero-3-phospho-ethanolamine, DHPE) in a lipid double layer membrane (palmitoyloleoylphosphocholine, POPC) at different concentration. From left to right: 10^3 dyes/μm^2, 10 dyes/μm^2, 10^{-2} dyes/μm^2. Each image was obtained with an epifluorescence microscope, illuminated by a defocused 514 nm Ar laser line ($\sim$60 kW/cm^2), and 5 ms integration on a nitrogen cooled CCD camera. Color scale: blue = 0, $d = 60$ counts). Image intensity at 10^3 dyes/μm^2 was divided by 60. (b) Sequence of three $5.4 \times 5.4\ \mu m^2$ images of two labeled lipids observed at 105 ms intervals (actual acquisition rate was one frame every 35 ms, integration time: 5 ms). (c) Subregion of a $2.4 \times 2.4\ \mu m^2$ membrane area showing the peak marked by a star in B. The nonlinear least-square fit of a two-dimensional Gaussian profile to the peak yields values of the fluorescence intensity $I = 168 \pm 25$ counts, width $r = 480 \pm 80$ nm and two-dimensional position with 40 nm resolution. Adapted from Schmidt T, Schutz GJ, Baumgartner W, *et al.* (1996) Imaging of single molecule diffusion. *Proceedings of the National Academy of Sciences USA* 93: 2926–2929. Copyright 1996, The Academy of Sciences.

parameters in the case of a confocal microscopy study of freely diffusing fluorescein isothiocyanate (FITC) in water, using avalanche photodiode detectors (APD) are: $E = 10^{-2}$, $Q = 0.85$, $\sigma = 2.8 \times 10^{-16}\,cm^2$, $A = 0.1\,\mu m^2$, $\lambda = c/\nu = 525\,nm$, $bV = 10$ Hz/μW, $D = 100$ Hz. With an excitation power of 100 μW and a 1 ms integration time, a count rate of 629 counts/ms can be obtained, of which 1 comes from the background sources, leading to a SNR $\sim$25 and SBR $\sim$629. Although these are acceptable figures, they have to be balanced by the fact that single molecules have a finite lifespan. Single molecules in an oxygen-rich environment typically emit on the order of 10^6 photons before irreversible degradation (photobleaching). With the above parameters, this amounts to a total emission of $\sim$3.2 ms. This is enough to observe freely diffusing molecules during their transit time of a few hundred microseconds. For a fixed molecule, however, it sets a stringent limit on the total duration of a single-molecule observation, and all efforts are put on reducing the excitation volume and intensity, as well as background sources. Similar considerations hold on the detector side, where a trade-off has to be found between time-resolution and quantum efficiency.

In addition to SNR and SBR issues, care has to be taken to ensure that the collected signal originates from a single molecule. Two different strategies can be envisioned:

(i) work at low concentration, such that at most one molecule is present in the excitation volume (**Figure 5b**), or equivalently, minimize the excitation volume;
(ii) use a selective excitation or emission detection protocol, such that only one molecule is excited or detected within the sampled volume (**Figure 5c**).

The first case has already been illustrated in **Figure 2**, in which a solution of fluorophores at low concentration yields separate bursts corresponding most of the time to transits of individual molecules. The second strategy can be adopted for the example illustrated in **Figure 1**, in which the ZPL of individual molecules lying in the wings of the ensemble spectrum are well separated. Tuning the laser to the peak absorption frequency of a molecule will excite this molecule only, allowing for a separate study of this molecule.

In summary, a set of six criteria can be defined for SMS:

1. The observed density of emitter is compatible with the known concentration of individual molecules and scales with the original concentration.
2. The observed intensity level is consistent with that of a single emitting molecule.
3. Each immobilized emitter has a well-defined absorption or emission dipole (for organic dyes usually linear, but for other emitters such as a fluorescent semiconductor nanocrystal, possibly circular).

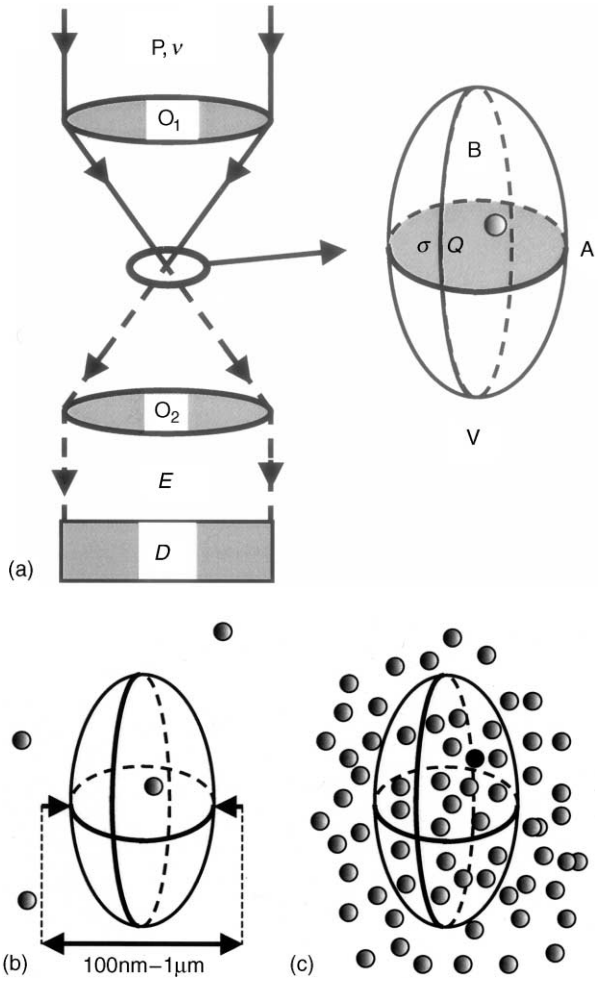

Figure 5 Signal, background and noise issues in single-molecule detection. (a) In a single-molecule spectroscopic experiment, excitation light (power P, frequency ν) is focused on the sample through an optical element O_1 (objective lens, fiber tip), exciting a diffraction-limited volume of section A, represented by an ellipsoid in the expanded view. The absorption process is characterized by an absorption cross-section σ and the emission by a quantum yield Q. The background contribution per watt of incident power is B, whereas the detector will have a dark count rate D. The signal is collected by an optical element O_2 (possibly confounded with O_1), and further guided to the detector, with an overall efficiency E. (b) The signal of a single molecule can be separated from that of other molecules if the probability of finding two or more molecules in the probed volume is negligible. This can be obtained either by a low concentration, or by reducing the excitation volume. (c) If each molecule in the excited volume can be characterized by a different spectral property (which may or may not depend on its exact environment), it is possible to use very selective excitation or detection techniques to probe just one molecule in the sampled volume (the black sphere in the ellipsoid).

4. Fluorescence emission exhibits only two levels (on/off) exemplified in blinking or photobleaching.
5. If there are more emission levels due to spectral jumps (see the section on fluorescence), blinking and spectral jumps are correlated.
6. Antibunching of the emitted photons permits us to test whether the detected signal comes from a single quantum emitter or more (see the section on biological studies below).

Types of Spectroscopy

Fluorophores

A variety of fluorescence emitters (or fluorophores) have been investigated with single-molecule spectroscopy techniques. Fluorescent organic molecules, green fluorescent proteins (GFP) and other biological fluorescent proteins, conjugated polymers (J-aggregates), light-harvesting complexes (e.g., B-phycoerythrin) comprising several fluorophores acting effectively as a single quantum emitter, or semiconductor nanocrystals, are but a few examples of systems which have been extensively studied. Each of these systems exhibits fluorescence based on specific processes, which cannot be described in detail here. A simple picture valid for single fluorescent dyes will be presented instead. It captures, however, the essential ingredients needed to describe the different parameters accessible with single-molecule spectroscopy.

Fluorescence Emission

Most single-molecule experiments use one-photon fluorescence excitation because of its relatively large cross-section ($\sim 10^{-16}$ cm^2). It also allows for a simple rejection of the excitation light: the emitted photons have a lower energy because of losses in intramolecular relaxation processes (the so-called Stokes shift). Excitation and emission processes are conveniently represented by a Jablonski diagram (Figure 6a) depicting the initial, final, and intermediate electronic and vibrational states of the molecule. Upon excitation to the first excited state, the molecule has a certain probability to be shelved in a nonemitting triplet state for up to milliseconds, resulting in 'dark' or off-states (Figure 6b,c). This results in a saturation of the emitted count rate R (Figure 6d) according to:

$$R = R_s \frac{I/I_s}{1 + I/I_s}, \qquad [3]$$

where the saturation intensity $I_s \sim 10-100$ kW/cm^2 and $R_s \sim 1-20$ MHz for typical fluorophores. Incidentally, this puts a limit in SNR enhancement due to saturation of the emitted signal (triplet bottleneck). Other fluorescence emitting 'single molecules' like semiconductor nanocrystals

exhibit similar dark state intervals, although for different reasons (Auger ionization or surface trapping of carriers). Finally, spectral jumps are also observed at room temperature (Figure 6e). This phenomenon results in a shift of absorption and emission maxima due to the changing environment of the molecule, or a sudden conformational change. The corresponding changes in excitation and emission spectra are noticed by sudden fluctuations in the emitted intensity

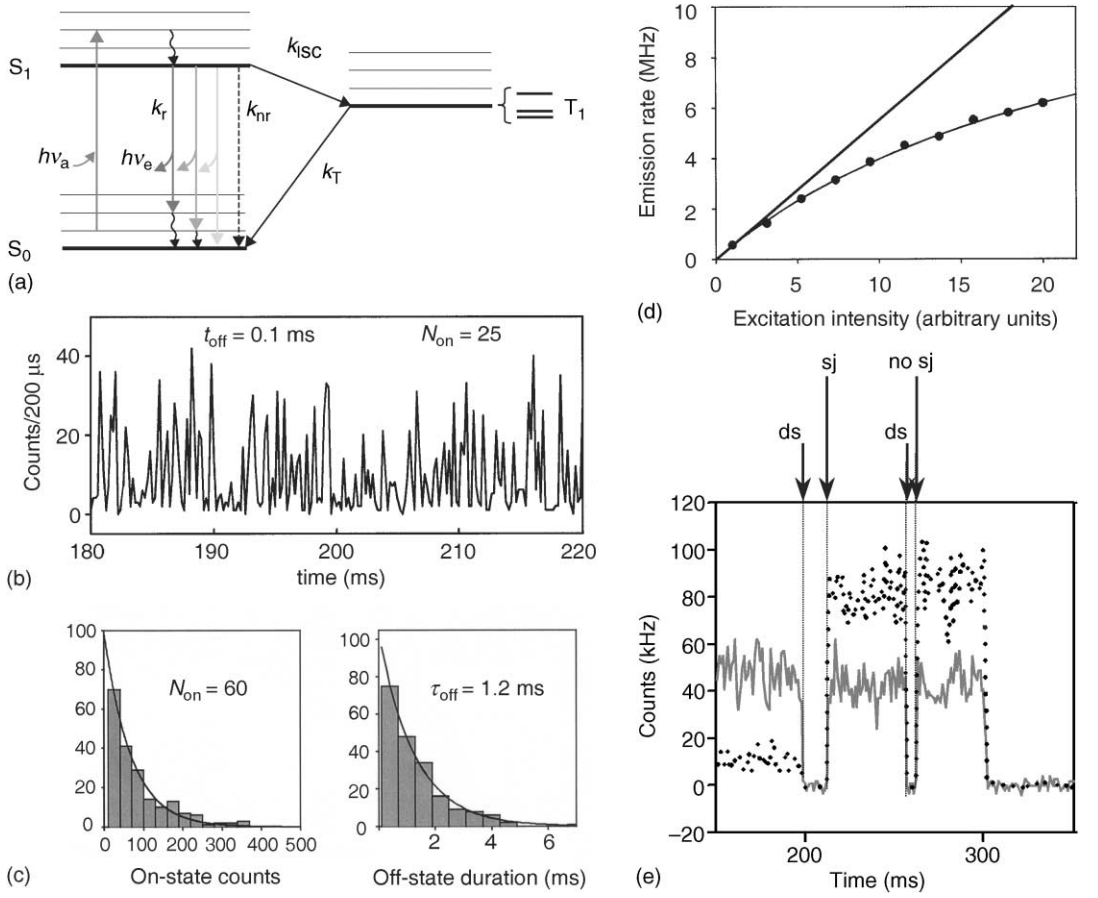

Figure 6 Single-molecule fluorescence. (a) Jablonski diagram for fluorescence (at room temperature). Upon absorption of a photon of energy $h\nu_a$ close to the resonance energy $E_{S_1} - E_{S_0}$, a molecule in a vibronic sublevel of the ground singlet state S_0 is promoted to a vibronic sublevel of the lowest excited singlet state S_1. Nonradiative, fast relaxation brings the molecule down to the lowest sublevel in picoseconds. Emission of a photon of energy $h\nu_e < h\nu_a$ (radiative rate k_r) can take place within nanoseconds and bring the molecule back to one of the vibronic sublevels of the ground state. Alternatively, collisional quenching may bring the molecule back to its ground state without photon emission (nonradiative rate k_{nr}). A third type of process present in organic dye molecules is intersystem crossing to the first excited triplet state T_1 (rate k_{ISC}). Relaxation from this excited state back to the ground state is spin-forbidden and thus the lifetime of this state is in the order of microseconds to milliseconds. Relaxation to the ground state takes place either by photon emission (phosphorescence) or nonradiative relaxation. The fluorescence lifetime is defined by $\tau = 1/\Gamma = (k_r + k_{nr})^{-1}$. (b) Fluorescence time trace (40 ms excerpt) of a Texas Red (TR) molecule attached to a 20-nucleotides-long single-stranded DNA molecule immobilized on a silanized glass coverslip. The confocal setup is similar to that depicted in Figure 2. Excitation: 514 nm, circularly polarized, 6 kW cm^{-2}, binning: 200 µs. On- and off-states (the latter corresponding to the molecule being in the triplet state) alternate stochastically. (c) Histograms of on-state count (left) and off-state duration (right) for the time trace partly shown in (b). The decay parameters of the exponential fits (solid line) are indicated. $t_{off} = 1.2$ ms is the triplet state lifetime. $N_{on}^{-1} = k_{ISC} = 1.7\%$. (d) Intensity dependence of the emission rate of a single Texas Red molecule. The data departs from a linear dependence because of saturation due to intersystem crossing. The fitted curve yields a saturation rate of $R_S = 6.5$ MHz and a triplet lifetime $t_{off} = (k_{ISC}\ R_S)^{-1} = 10$ µs. The difference between this value and the value obtained in (c) illustrates the heterogeneity uncovered by single-molecule measurements. (e) Spectral jumps of a single Texas Red molecule attached to a single-stranded DNA molecule. ds: dark state, sj: spectral jump, no sj: dark state not followed by a spectral jump. Cases where spectral jumps are observed without noticeable dark states may still correspond to dark states with durations shorter than the time resolution of the experiment. (b)–(d) Adapted from Ha T, Enderle T, Chemla DS, *et al.* (1997) Quantum jumps of single molecules at room temperature. *Chemical Physics Letters* 271: 1–5. Copyright 1997, Elsevier Science B. V. (due to wavelength dependence of the absorption cross-section).

Fluorescence Lifetime

A fluorescence photon is emitted within nanoseconds after absorption of the excitation photon. The decay law is usually mono-exponential, characterized by a lifetime $\tau = \Gamma^{-1}$ (Figure 6a). However, the lifetime depends on the emission spectrum (which can change due to spectral shifts) and the local environment. For instance, the proximity to a dielectric or metallic surface markedly changes it via perturbations of the intramolecular transition matrix elements. Thus, fluorescence lifetime is a sensitive probe of the environment of the molecule (Figure 7). Lifetime measurements require a pulsed laser source and time-correlated single-photon detection and analysis techniques.

Fluorescence Polarization

The efficiency of photon absorption by a fluorescent molecule is proportional to $(\boldsymbol{E}\cdot\boldsymbol{\mu})^2$ where $\boldsymbol{E}$ represents the local electric field and $\boldsymbol{\mu}$ the molecule's absorption dipole moment. For a fixed fluorophore, modulation of the excitation polarization thus allows the determination of the absorption dipole orientation (the emission dipole being generally nearly parallel to it). This information in turn allows the determination of the spatial orientation of the molecule. For a mobile molecule, however, more information is needed, since the emission dipole has time to tumble significantly during the few nanoseconds between absorption and emission. The emission polarization is needed to fully recover the relevant information, as illustrated in Figure 8. Different experimental schemes can be used, besides the near-field optical one described in Figure 3 and the confocal one described in Figure 8. In particular, it is important to recover the projection of the polarization on more than two orthogonal axes. Approaches taking advantage of aberrations induced by index mismatch in high numerical aperture (NA) objectives, or using TIR excitation with alternating polarizations, or using amplitude or phase masks, allow a complete determination of this orientation.

Fluorescence Resonance Energy Transfer

A special case of the local influence of the environment on fluorescence is encountered in fluorescence resonance energy transfer (FRET, see Figure 9a), first theoretically explained by Förster in the late 1940s. In case of the presence of a nearby molecule (acceptor) having an absorption spectrum overlapping that of the donor emission, there is a possibility that the energy absorbed by the donor is transferred nonradiatively to the acceptor. The efficiency E of this transfer is given by:

$$E = \left(1 + \left(\frac{r}{R_0}\right)^6\right)^{-1} \qquad [4]$$

where r is the distance between the two emitting centers and R_0 is the Förster radius (in Å):

$$R_0 = a(\kappa^2 n^{-4} Q_D J(\lambda))^{1/6} \qquad [5]$$

In this complex expression, $a = 9.78 \times 10^3$, n is the medium refractive index, Q_D the donor fluorescence quantum yield in the absence of the acceptor and $J(\lambda)$ is a spectral overlap integral (in M^{-1} cm^3). κ^2 is a geometric factor, which averages out to 2/3 in the case of freely rotating dyes. A typical order of magnitude for R_0 is a few nanometers, which gives the range of the energy transfer. FRET is thus very sensitive to the donor–acceptor distance, which makes it a useful molecular ruler. Experimentally, the efficiency is measured as a function of the recorded donor (F_D) and acceptor (F_A) emissions (dual-channel measurement) via:

$$E = \left(1 + \alpha \frac{F_D}{F_A} \frac{Q_A}{Q_D}\right)^{-1} \qquad [6]$$

where Q_A and Q_D are the fluorescence quantum efficiencies of the donor and acceptor, respectively, and α is the ratio of the acceptor and donor channel detection efficiencies. An illustration of this utilization is given in Figure 9b–d, where different predefined distances between donors and acceptors are set by rigid double-stranded DNA molecules. The corresponding donor–acceptor distances are readily measured on diffusing molecules, with subnanometer precision.

Alternatively, the transfer efficiency can be measured via the fluorescence lifetimes as:

$$E = 1 - \frac{\tau_{D(A)}}{\tau_{D(0)}} \qquad [7]$$

where $\tau_{D(A)}$ and $\tau_{D(0)}$ are the donor lifetimes in the presence or absence of an acceptor, respectively.

Other Spectroscopies

Other types of spectroscopic techniques can be used at the single-molecule level. Fluorescence can for instance be excited via a two-photon absorption process, whereby a laser excitation with half the photon energy needed to attain the excited state

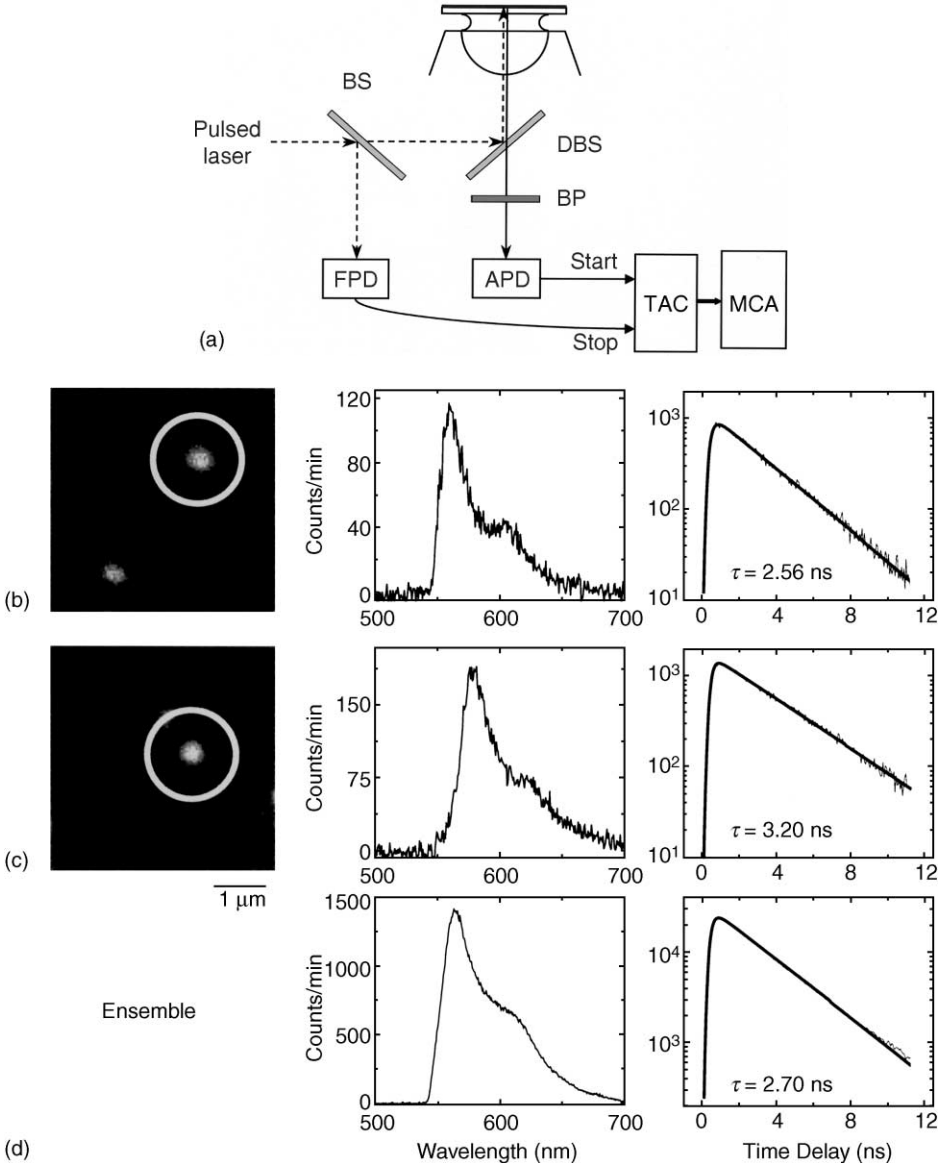

Figure 7 Lifetime measurements. (a) Schematic of a lifetime measurement setup. BS: beamsplitter used to deflect part of the incident pulse towards a fast photodiode (FPD); DBS: dichroic beam splitter used to spectrally separate incident from emitted light; BP: bandpass filter further rejecting stray light; APD: avalanche photodiode. For each detected photon, the APD emits a pulse, which is fed to the start input of a time-to-amplitude converter (TAC). A stop pulse from the laser immediately follows it (regularly emitted at a rate of τ_L^{-1}), allowing the measurement of the separation between both pulses. A multichannel analyzer (MCA) histograms the arrival times, resulting in the curves shown in the right part of Figure 2b–d. (b) and (c) Fluorescence images (left panels), corresponding spectra (middle), and fluorescence decays (right) for two molecules located at a PMMA–air interface. The peak emission wavelength λ_p was 560 nm in (b) and 578 nm in (c). Lifetimes were fitted to a single exponential (dotted curves), with decay times of $\tau = 2.56$ ns (b) and 3.20 ns (c). A ensemble measurement of spectrum and fluorescence decay averaged over several hundred of molecules is shown in (d). The ensemble values are $\lambda_p = 565$ nm and $\tau = 2.70$ ns. (b)–(d): Adapted from Macklin JJ, Trautman JK, Harris TD and Brus LE (1996) Imaging and time-resolved spectroscopy of single molecules at an interface. *Science* 272: 255–258. Copyright 1996, The American Association for the Advancement of Science.

is used. However, due to the very low cross-section and quadratic dependence in the incident energy (two simultaneous photons are needed for excitation), an excitation power several orders of magnitude larger than that for one-photon excitation is needed. In compensation, excitation takes place in a much more reduced volume of the sample, reducing the out-of-focus background contribution. The higher power required increases the probability of photobleaching due to the increased probability of

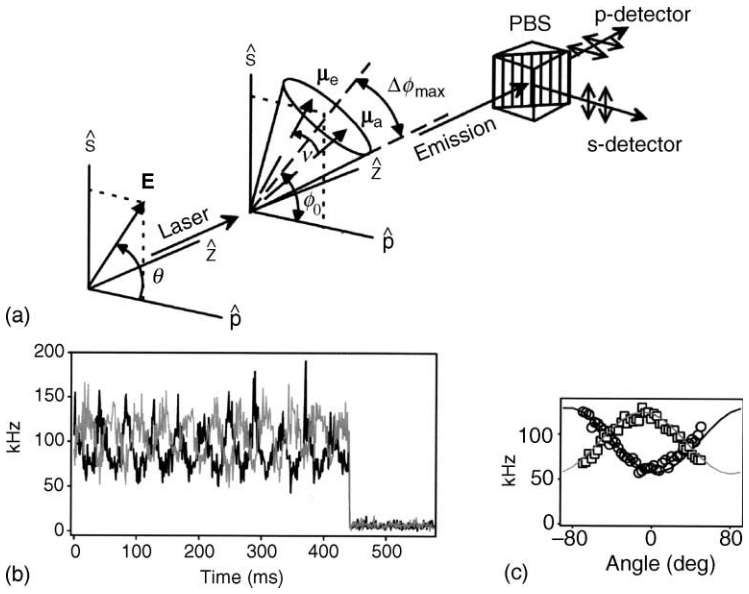

Figure 8 Polarization Measurements. (a) Experiment schematic. **E** is the electric field, making an angle θ with the *p* polarization axis. The excitation propagates along the *z* axis, which is also the collection axis. $\boldsymbol{\mu}_a$ and $\boldsymbol{\mu}_e$ are the absorption and emission dipole moments, initially aligned. ν represents the rotational diffusion of the emission dipole during the excited lifetime. The dipole is supposed to be confined in a cone positioned at an angle ϕ_0 projected on the (*s*, *p*) plane, and having a half-angle $\Delta\phi_{max}$. A polarizing beam-splitter (PBS) splits the collected emission into two signals I_s and I_p, which are simultaneously recorded by APDs. (b) Simultaneously recorded I_s (black) and I_p (gray) of a molecule rapidly rotating in a liquid. (c) Same data as in (b), but averaged over 11 on-periods. The fit corresponds to a $\Delta\phi_{max}$ close to 90° (freely rotating molecule) and permits the determination of the constrained rotational diffusion parameters. Adapted from Ha T, Glass J, Enderle T, *et al.* (1998) Hindered rotational diffusion and rotational jumps of single molecules. *Physical Review Letters* 80: 2093–2096. Figure 9 Single pair fluorescence resonance energy transfer. (a) Jablonski diagram for FRET. Fluorescence energy transfer involves two molecules: a donor D and an acceptor A whose absorption spectrum overlaps the emission spectrum of the donor. Excitation of the acceptor to the lowest singlet excited state is a process identical to that previously described for single-molecule fluorescence (**Figure 6a**). In the presence (within a few nm) of a nearby acceptor molecule, donor fluorescence emission is largely prevented by energy transfer to the acceptor by dipole–dipole interaction. The donor exhibits fluorescent emission following the rules outlined in **Figure 6a**. (b) DNA *n* constructs used for the FRET distance study. Tetramethylrhodamine (TMR) is attached to one end of the DNA and CY5 is attached to the *n*th base from the end ($n = 7$, 12, 14, 16, 19, 24 and 27). (c) FRET histograms extracted from time traces for DNAs 7, 12, and 19, as shown in **Figure 2b**. Double Gaussian fits extract numbers for the mean (width) of the higher efficiency peak of 0.95 ± 0.05, 0.75 ± 0.13, and 0.38 ± 0.21, respectively. The peak around 0 efficiency corresponds to bleached or inactive acceptor molecules. (d) Mean FRET efficiencies extracted from FRET histograms plotted as a function of distance for DNA 7, 12, 14, 16, 19, 24, and 27. Distances are calculated using the known B-DNA double helix structure. The solid line corresponds to the expected Förster transfer curve with $R_0 = 65$ Å. (b)–(c) Adapted from Deniz AA, Dahan M, Grunwell JR, *et al.* (1999) Single-pair fluorescence resonance energy transfer on freely diffusing, molecules: Observation of Förster distance dependence and subpopulations. *Proceedings of the National Academy of Sciences USA* 96: 3670–3675. Copyright 1999, The National Academy of Sciences.

photochemical degradation in the long-lived triplet state and the interplay of multiphoton ionization processes.

Although Raman scattering cross-sections ($\sim 10^{-30}$ cm^2) are orders of magnitude lower than the fluorescence cross-section, they can be enormously amplified if the single molecule is trapped in a 'hot spot' of a metallic nanoparticle, giving rise to surface-enhanced Raman scattering (SERS). Highly resolved vibrational information can be recovered, exhibiting much more stable emission than fluorescence. Moreover, this technique can be applied to nonfluorescent molecules. Similarly to fluorescence, the technique can be extended to nonlinear (two-photon) regimes, as in surface-enhanced hyper-Raman scattering and surface-enhanced anti-Stokes Raman scattering. However, since they require the single molecule to be located on rare sites of a metallic particle, these methods have only been applied to fundamental chemical studies of molecular species.

Finally, extending the range of the FRET 'molecular ruler', electron transfer allows measuring distances between an electron donor and an acceptor within a few ångströms (Å), via opening of a nonradiative channel for the relaxation of the electron in the excited state. Lifetime measurements ($\tau = 1/\Gamma = (k_r + k_{nr})^{-1}$ as defined in Figure 6) yield distance information via the electron transfer rate E_{ET}:

$$E_{ET} = k_0 e^{-\beta r}, \qquad [8]$$

where β^{-1} is of the order of one Å and k_0 of the order of 10^{15} s^{-1} are constants characterizing the donor–acceptor pair.

Applications of Single-Molecule Spectroscopy

Single-molecule spectroscopy has already proven to be a useful tool in various domains. The following examples are but a few of an expanding number of applications of SMS.

Molecular Physics

The realization that the fluorescence of a single molecule could be detected with a good SNR over extended periods of time, especially embedded in a crystalline matrix at cryogenic temperature, has led to high-resolution experiments aimed at determining molecular energy levels and transitions. In particular, studies of transitions between sublevels of the triplet state by electron spin resonance (ESR) using superimposed radio-frequency pulses have permitted a precise test of the quantum description of such systems. The dc and ac Stark effect (the shift of a transition energy in the presence of a fixed or alternating electric field) has also been studied in several systems, allowing the symmetry and deformations of the molecule to be determined. The method has been extended to study the photophysics of luminescent polymers (J-aggregates), light-harvesting complexes, green fluorescent proteins (GFP) or semiconductor nanocrystals, and other fundamental systems.

Material Science Studies

Single-molecule photophysical properties are extremely sensitive to their local (nanometer-sized) environment (Figure 1). A precise knowledge of these properties allows using single molecules as sensitive probes of their environment, as illustrated by experiments designed to study the local dynamics of a polymer matrix at the onset of the glass transition (Figure 10).

Molecules of the organic fluorophore Rhodamine 6G (R6G) dispersed within a thin (250 nm) poly(methacrylate) film were observed at temperatures slightly above the melting temperature of the polymer, using a confocal microscope detecting the s and p polarization of the emitted fluorescence (Figure 8a). Observations are performed under nitrogen atmosphere and at low excitation power (20 nW) in order to prevent oxidation, thus allowing long (several hours) observation time. Each observed R6G molecule exhibits a slow rotational diffusion, sometimes accompanied by lateral or transverse diffusion on a much longer time-scale (Figure 10a). Computation of the autocorrelation function of the emission polarization shows a multi-exponential decay, pointing to a distribution of time-scales of rotational diffusion. A closer look at subwindows of the time trace reveals, however, that the decay comes closer to mono-exponential behavior at shorter time-scales (Figure 10b,c). This study demonstrates that an individual molecule probes an increasing number of different environments over time. At long time-scales, the observable characteristics (such as the autocorrelation function) are similar to those measured on an ensemble of molecules, as expected from the ergodicity hypothesis. At short time-scale, the molecule reveals the local homogeneous and stable characteristic of its nanoenvironment.

Biophysical and Biological Studies

SMS has allowed a reassessment of long-standing questions in biophysics, biochemistry, and biology, by giving scientists the possibility to look at individual building blocks of biological processes: DNA, RNA, proteins and other biomolecules or biomolecular

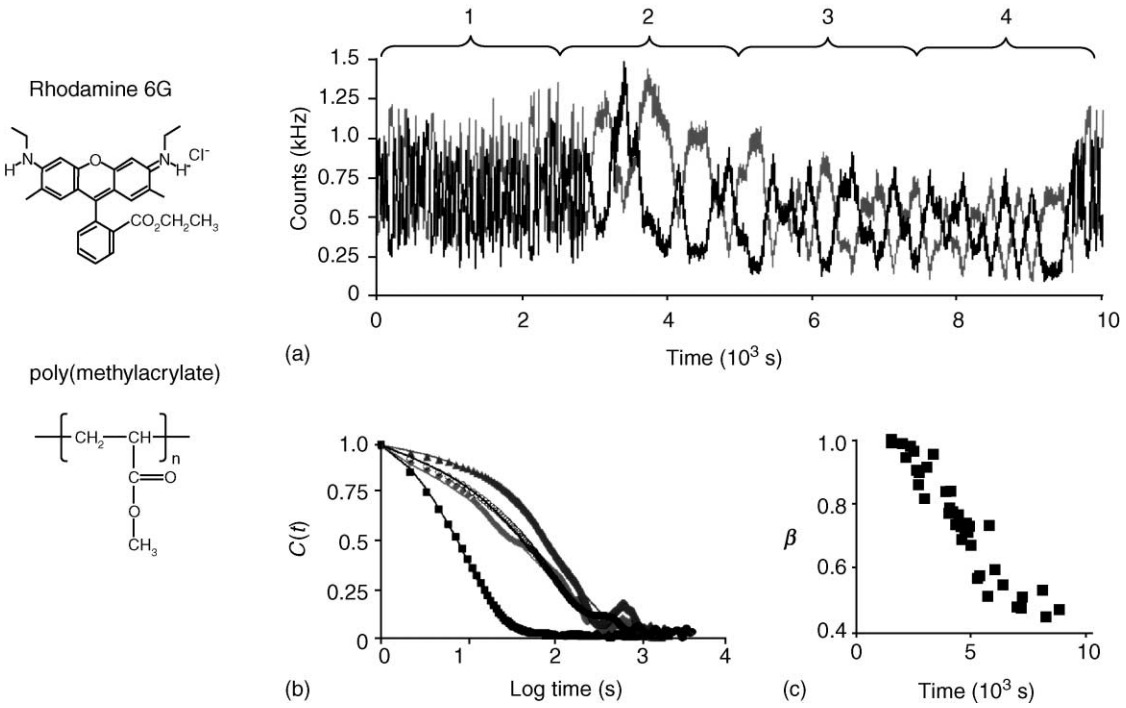

Figure 10 Polymer dynamics near the glass transition. (a) Fluorescence intensity of a single long-lived Rhodamine 6G molecule in poly(methylacrylate) (PMA) at 291 K detected at orthogonal polarizations (gray: *s* and black: *p* polarizations). The melting temperature of PMA is $T_g = 281$ K. The time trace integration is 1 s. This time trace shows the anticorrelation of both polarizations, characteristic of rotational diffusion of the molecule. Different regimes are observed along the time trace (1–4), which could be due to either a modification of the local 'cage' in which the molecule rotates, or escape of the molecule to another nearby nano-environment. The autocorrelation function of polarization computed over the whole trace (not shown) is well fitted by a model adapted to the nonexponential relaxation of polymers, the Kohlrausch–Williams–Watt (KWW) model:

$$\mathrm{KWW}(t) \propto \mathrm{e}^{-(t/\tau)^{\beta}}.$$

with $\tau = 88$ s, $\beta = 0.46$. (b) Correlation functions of subsets 1–4 of the full trace. 1 (squares): $\tau = 15$ s, $\beta = 1.0$. 2 (triangles): $\tau = 112$ s, $\beta = 0.77$. 3 (open circles): $\tau = 90$ s, $\beta = 0.59$. 4 (diamonds): $\tau = 64$ s, $\beta = 0.59$. The β exponent is closer to 1, showing that the rotational diffusion is an unhindered one at short time-scales, converging to the bulk exponent at larger time-scale due to ergodicity. This experiment illustrates changes of environment as the observed molecule diffuses and rotates through the polymer mesh, changes that are hidden in ensemble measurements. (c) Values of β as a function of photochemical survival time in PMA at $T_g + 5$ K. complexes formed by association of a few of these molecules.

To simplify the task, some biological molecules are intrinsically fluorescent in their active state, as the cholesterol oxidase (COx) enzyme of Brevibacterium sp., an enzyme that catalyzes the oxidation of cholesterol by oxygen. As a result, it is relatively easy to study the dynamics of this enzyme at the single-molecule level using a confocal setup with enzymes immobilized in an agarose gel (Figure 11). The intervals during which the enzyme is active ('on' state) are followed by intervals during which it is inactive ('off' states). The fluorescence recording of a single enzyme thus appears as a 'blinking' time trace, as shown in Figure 11b. Relevant kinetic parameters can be extracted from the distribution of 'on' and 'off' times. Apart from the usual heterogeneity between enzymes of the same batch characterized by different kinetic parameters for the catalysis reaction, this experiment reveals a dynamic heterogeneity, which shows up for each individually studied enzyme as a tendency for short 'on' times to follow short 'on' times, and for long 'on' times to follow long 'on' times (Figure 11c). This variable behavior of a single enzyme is reminiscent of the variable rotational dynamics of Rhodamine 6G molecules in a polymer matrix (see the previous section), and can be studied only thanks to single-molecule techniques.

Not all biological molecules can be studied in such a convenient way using their intrinsic fluorescence. Several labeling schemes are currently available, which allow quantitative, site-specific labeling of proteins, nucleic acid or lipid molecules with few biochemical side effects.

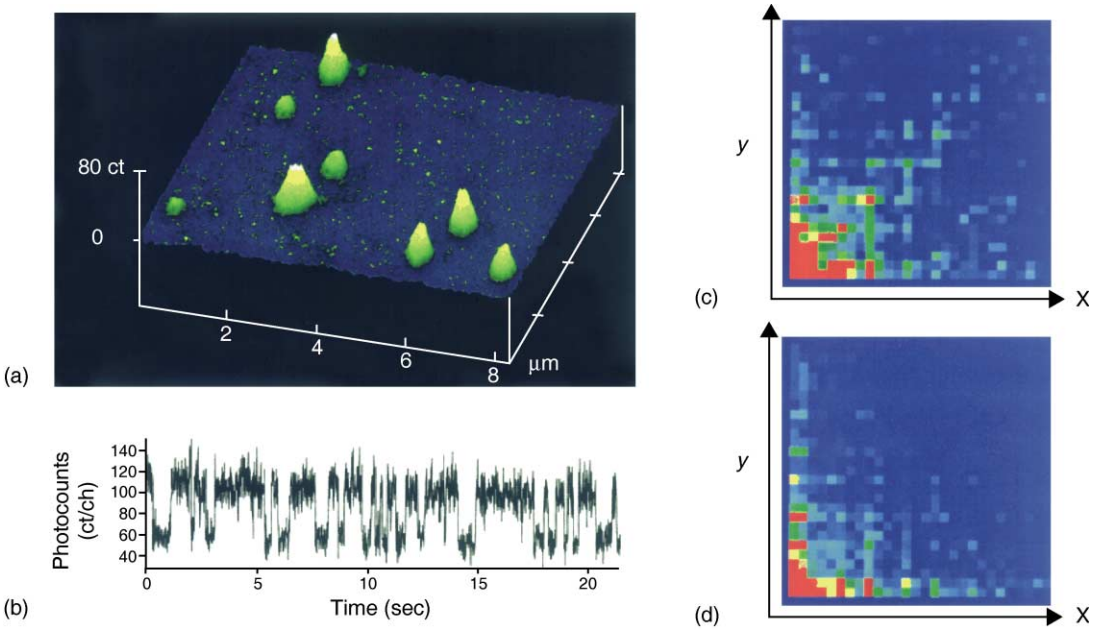

Figure 11 Single-enzyme dynamics. (a) Fluorescence image of single CO_x molecules immobilized in a 10-μm-thick film of agarose gel of 99% pH 7.4 buffer solution (8 μm × 8 μm, 4 min scan, 500 nW excitation at 442 nm). The emission is from the fluorescent active site, FAD, which is tightly bound to the center of CO_x. Each individual peak is attributed to a single CO_x molecule. The intensity variation between the molecules is due to different vertical positions in the excitation volume. (b) Real-time observation of enzymatic turnovers of a single CO_x molecule catalyzing oxidation of cholesterol molecules. This panel shows a portion of an emission intensity trajectory recorded in 13.1 ms per channel. The trajectory was recorded with a cholesterol concentration of 0.2 mM and saturated oxygen concentration of 0.25 mM. The emission exhibits stochastic blinking behavior as the flavin adenine dinucleotide (FAD), the CO_x fluorescent active site toggles between oxidized (fluorescent) and reduced (nonfluorescent) states, each on–off cycle corresponding to an enzymatic turnover. More than 500 on–off cycles are recorded in this trajectory. (c) The 2D conditional probability distribution for on-times (x and y) of two adjacent turnovers as derived from the trajectories of 33 CO_x molecules with 2 mM 5-pregene-3β-20α diol substrate, a derivative of cholesterol. The scales of the x- and y-axes are from 0 to 1 s. A subtle diagonal feature is present, indicative of a memory effect. (d) The 2D conditional histogram for two on-times separated by 10 turnovers for the CO_x molecules in (c). The diagonal feature vanishes because the two on-times become independent of each other at the 10-turnover separation. The color code in (c) and (d) represents the occurrence (z-axis from 350 (red) to 0 (purple). Adapted from Lu HP, Xun L and Xie XS (1998) Single-molecule enzymatic dynamics. *Science* 282: 1877–1882. Copyright 1998, The American Association for the Advancement of Science.

An example of this versatility has been provided by the labeling of the central part of a rotary protein, F_1-ATPase. In this experiment (not shown), the molecular rotor was labeled with a single fluorophore whose orientation, detected by emission polarization measurements, directly reported the angle of the rotor with respect to the shaft. The small size of the fluorophore guaranteed that the protein motion would not be hindered, contrary to previous experiments, which used much larger reporters (micron-size latex beads or fluorescent actin filaments). This experiment reproduced the previous results, showing that the rotor performed 120° steps (recent work hints at substeps of 90° and 30°).

One of the most promising domains where SMS can be of great importance is the study of protein folding. Doubly labeled proteins can be monitored as they undergo conformational changes, taking advantage of the distance dependence of fluorescence energy transfer (demonstrated for a model DNA system in the section on FRET, Figure 9).

Figure 12 shows one of many examples of such a study, performed on diffusing molecules in solution, a configuration that suppresses uncontrolled effects of nearby surfaces. The enzyme chymotrypsin inhibitor 2 (CI2) is a model system for protein folding, believed to have two clearly distinct folding states, which can be controlled by the concentration of denaturant guanidinium chloride. Using single-pair FRET (spFRET) techniques, it is possible to sort out the proportion of folded and unfolded molecules present at different denaturant concentration (Figure 12b). These measurements yield the same titration curve as obtained by ensemble measurements (Figure 12b) and can give access, under some simplifying assumptions, to the energy landscape of the folding reaction. The additional information provided by spFRET is

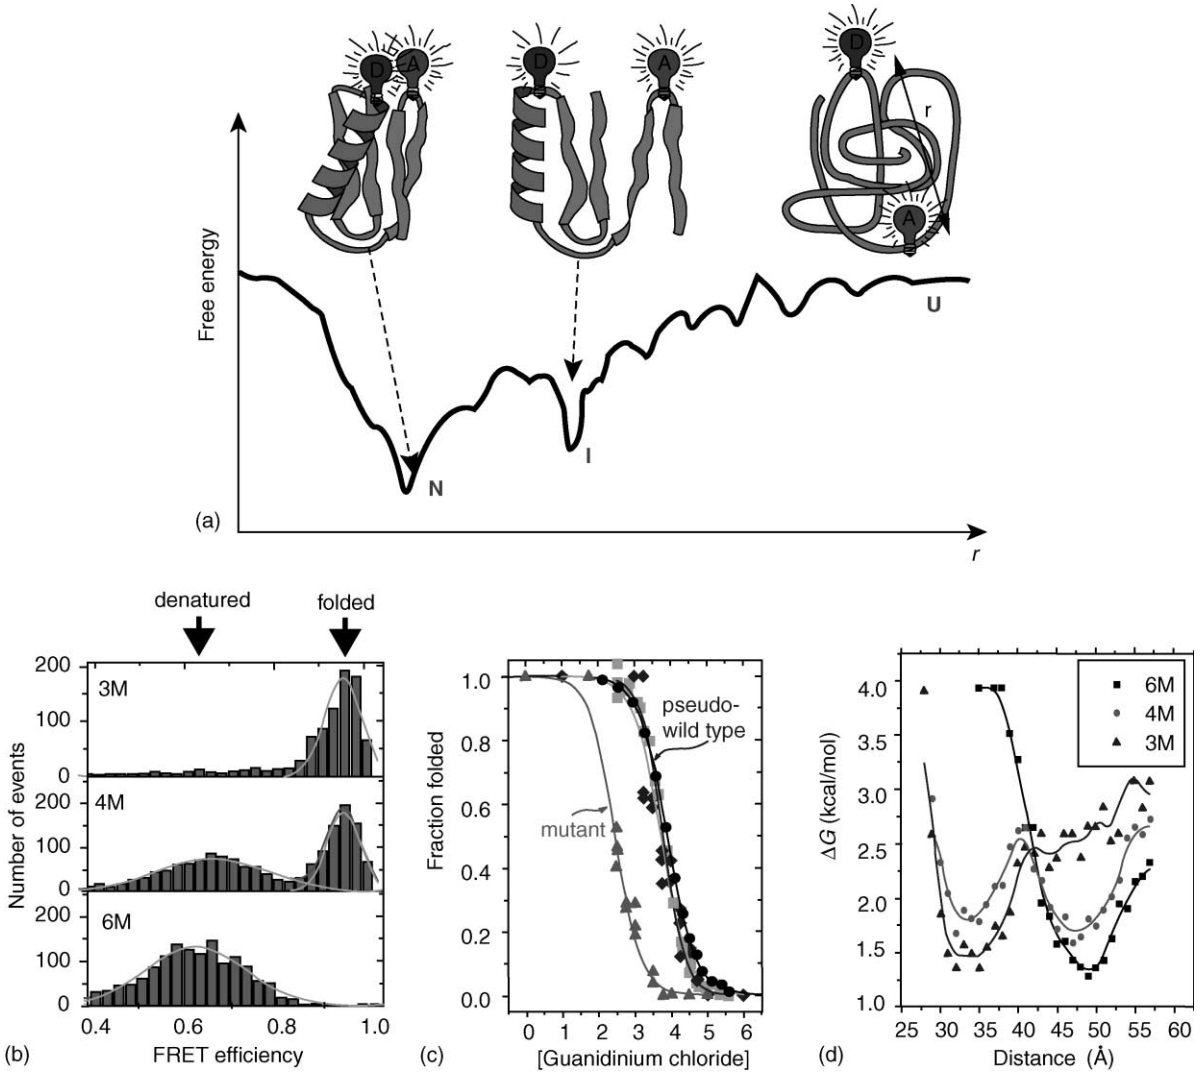

Figure 12 Protein folding. (a) Energy landscape for a protein folding reaction represented as a cartoon of the free energy as a function of distance *r* between donor and acceptor. The rugged energy landscape has a funnel shape with three extrema: U (unfolded state), I (intermediate state) and N (folded or native state). In this labeling scheme, donor and acceptor are close to one another in the native, folded state (N), resulting in a high FRET efficiency. There is reduced energy transfer (larger distance) in the denatured, unfolded state (U). (b) Single-molecule protein folding data. Single-pair FRET (spFRET) histograms of the pseudo-wild type enzyme chymotrypsin inhibitor 2 (PWT CI2) at 3, 4, and 6M denaturant (guanidinium chloride). The FRET efficiency exhibits two peaks, one for folded molecules (high FRET) and one for unfolded molecules (low FRET). Population is transferred from folded to unfolded at higher denaturant concentration, as expected from the protein labeling schematically depicted in (a). (c) Ensemble and single molecule denaturation curves for PWT and K17G mutant CI2. Symbols correspond to data; lines showing sigmoidal fits. PWT CI2: ensemble tryptophan fluorescence experiment (circles), ensemble FRET (squares), spFRET (diamonds); K17G mutant CI2 spFRET (triangles). (d) Free energy functions for PWT CI2 at 3, 4, and 6M denaturant. The solid lines represent a smoothing of the data and are only meant to guide the eye. the number of molecules in the two different states, providing direct evidence of the two-states model hypothesized from ensemble measurements.

Other biological systems have been addressed using the spFRET approach. Intramolecular spFRET (used in the CI2 study) allows monitoring conformational changes, whereas by labeling two different molecules, intermolecular spFRET permits the detection of association and dissociation events. For instance, spFRET has revealed transient intermediate states in

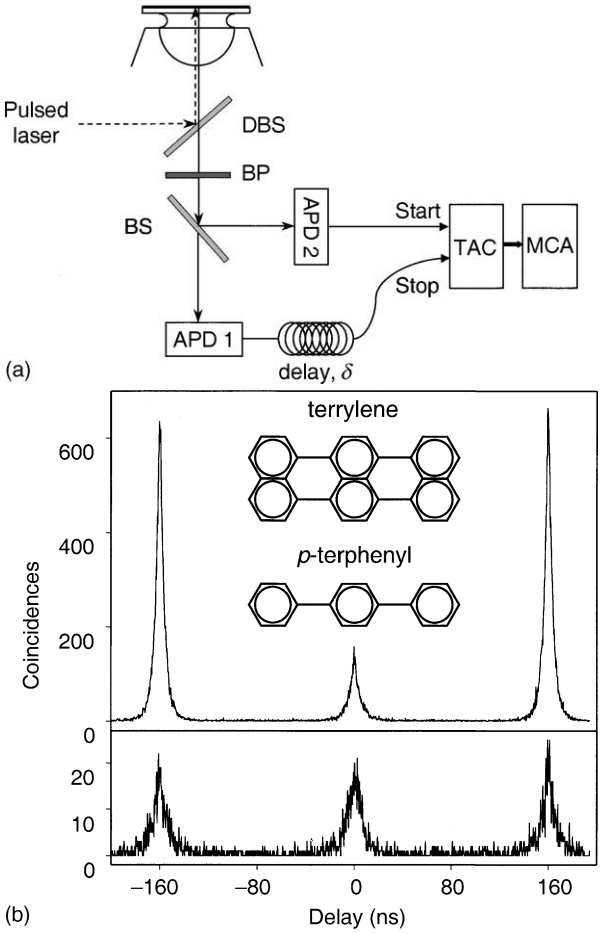

Figure 13 Single-photon source at room temperature. (a) Antibunching measurement setup. The basic elements are similar to those of a lifetime measurement setup (**Figure 7a**) except that the emitted filtered signal (BP: bandpass filter) is split in two with a 50/50 beamsplitter (BS). Two avalanche photodiodes (APD) detect the arrival of photons. One APD pulse is used as the start signal for a time-to-amplitude converter (TAC), which is stopped by the pulse coming from the second APD. Since the TAC response time is finite, it cannot detect simultaneously arriving pulses. A delay time δ is thus added to the stop signal, such that two photons impinging simultaneously on the two APDs will generate pulses with a separation of δ. If the start APD detects a photon from the previous excitation, the measured delay will be 160 ns $+ \delta$, whereas if the opposite happens, the delay will be $\delta - 160$ ns. (b) Results of measurements on a terrylene molecule (upper chemical structure) embedded in a p-terphenyl (lower chemical structure) at room temperature. Upper panel: histogram of delay measurements shifted by an amount δ. The histogram corresponds to 120 s of recording on an isolated emitting spot. The residual central peak corresponding to coincidence of photon arrival at APD 1 and 2 is the result of background contamination. Lower panel: histogram acquired over 300 s on a background spot. In both measurements, the laser pulse width was 35 ps, each pulse being separated by 160 ns. The lifetime of terrylene is measured to be 3.8 ns, which sets the width of the observed peaks. Excitation is performed at 532 nm. (b): Adapted with permission from Lounis B and Moerner WE (2000) Single photons on demand from a single molecule at room temperature. *Nature* 407: 491–493. Copyright 2000, Nature Publishing Group.

the Tetrahymena ribozyme, which had remained unnoticed in ensemble studies.

Quantum Optics

Low-temperature spectroscopic studies of single molecules have turned into a benchmark for testing predictions of quantum mechanics. In particular, one effect expected for a single quantum emitter is the absence of simultaneous emission of two photons: a fluorescent system which is excited at time t_0 has to emit a photon before it can return to the ground state, and be re-excited at a later time t_1. In conditions where the excitation takes place immediately as the electron returns to the ground state, the time difference $t_1 - t_0$ is of the order of the excited state lifetime, of the order of a few nanoseconds. This antibunching phenomenon was first observed in atoms and ions, and rapidly confirmed by low-temperature SMS. This observation is possible either using continuous wave or using pulsed excitation. In fact, nothing prevents this effect from occurring at room temperature, as demonstrated in **Figure 13** for pulsed excitation in which excitation photons are provided as well-separated bunches of a few hundred femtoseconds duration.

In this experiment, a system originally used at low temperature (terrylene in a crystal of p-terphenyl) is excited with a repetition rate of 6.25 MHz. The fluorescence emitted by a single molecule is detected in a confocal setup, split in two and directed to two different detectors (**Figure 13a**). In this way, the time interval between each pair of photons detected by the two detectors can be precisely measured and histogrammed. The result of this time-correlated single-photon counting approach is the absence of coincidence of two photons (**Figure 13b**), besides the residual counts due to background contamination.

Since the quantum efficiency of this system is high, the experimental setup can be seen as a periodic single-photon source, with an extremely low probability for the simultaneous emission of two photons. This is precisely the kind of device that is needed for quantum cryptography, in which information encoded in the polarization of a beam should not be sensitive to a 'beamsplitter' attack. Future efforts will undoubtedly build on such 'turnstile' photon sources to move forward into optical quantum computing applications.

Perspectives

SMS is a mature discipline, which will certainly prove to be most useful in domains beyond those previously mentioned. Its relative ease of implementation will

certainly attract more scientists of other disciplines to this methodology, each of them having specific goals in mind that are difficult to foresee. The principal advantages of SMS outlined at the beginning of this article will remain, but improvements, especially towards simultaneous acquisition of all the fluorescence parameters described earlier are promising. New detectors will permit the combination of the high time resolution of single-photon counting devices with the large field of view and spectral resolution allowed by two-dimensional detectors. SMS will be associated with single molecule manipulation techniques, to correlate applied forces and molecular conformations. New ways of controlling local fields (electric, magnetic, or others) would take advantage of the non-invasiveness, high-temporal and spatial resolution of SMS to get a direct feedback of events at the nanometer scale. Undoubtedly, SMS will be a major tool in the future of nanotechnology.

List of Units and Nomenclature

Å	Ångström
cm^2	square centimeter
fl	femtoliter
K	kelvin
ms	millisecond
MHz	megahertz
μW	microwatt
nm	nanometer

APD	Avalanche photodiode
DNA	Deoxyribonucleic acid
FRET	Fluorescence resonance energy transfer
NA	Numerical aperture
PMMA	Polymethylmethacrylate
SERS	Surface-enhanced Raman scattering
SMS	Single-molecule spectroscopy
SNR	Signal-to-noise ratio
SNE	Signal-to-background ratio
TIR	Total internal reflection
ZPL	Zero phonon line

Introduction

Terahertz (THz) radiation is usually referred to as an electromagnetic wave with frequencies ranging from 1 to a few terahertz ($1\,\text{THz} = 10^{12}\,\text{Hz}$). In the electromagnetic spectrum, terahertz radiation lies between the infrared and microwave, as shown in Figure 1. The techniques for generation and detection of THz radiation bridge photonics and electronics in the sense of the concepts and the techniques discussed below.

Physical quantities corresponding to 1 THz are listed as follows;

- Frequency, 1 THz
- Wavelength, 300 μm
- Wavenumber, 33 cm^{-1}
- Energy, 4.1 meV
- Temperature, 48 K

In this spectral region, there exist many rich physical, chemical, and biological phenomena. For example, many phonon resonance and other elementary excitations in condensed matter fall in this region; many molecular vibrations and rotations occur at THz frequency; conformation-related collective vibrational modes in macromolecules, especially in bio-molecules such as proteins and DNA, also lie in THz frequency. However, the development of THz technique lags far behind that of photonics and electronics, due to lack of feasible, reliable, and economic coherent THz sources. The situation has been rapidly changing since the 1990s. Benefiting from advanced material science and the ultrafast laser techniques, various coherent THz sources are being developed and commercialization is soon to follow. We will introduce these coherent THz sources and their main features, and discuss their generation mechanisms. More details can be found in the listed books and articles in the Further Reading section at the end of this article.

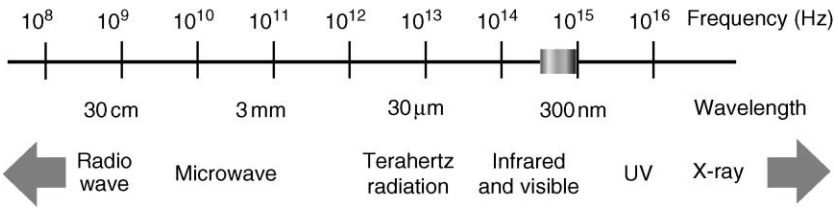

Figure 1 The electromagnetic spectrum with THz radiation sitting between the microwave and the infrared.

Coherent THz Radiation

When a time varying polarization, $\mathbf{P}(\mathbf{r},t)$, is generated in a medium and oscillates at THz frequency, it will radiate a THz wave, $\mathbf{E}(\mathbf{r},t)$, according to Maxwell's equation:

$$\nabla \times \nabla \times \mathbf{E}(\mathbf{r},t) + \frac{1}{c^2}\frac{\partial^2}{\partial t^2}\mathbf{E}(\mathbf{r},t) = -\mu_0 \frac{\partial^2}{\partial t^2}\mathbf{P}(\mathbf{r},t) \quad [1]$$

or

$$\nabla \times \nabla \times \mathbf{E}(\omega) - \frac{\omega^2}{c^2}\mathbf{E}(\omega) = \omega^2 \mu_0 \mathbf{P}(\omega) \quad [2]$$

in frequency domain, for a monochromatic wave or a Fourier component of a wave with a finite bandwidth. The properties of THz radiation are determined by the polarization source $\mathbf{P}(\mathbf{r},t)$. Incoherent THz sources exist in blackbody radiation, and are also detected in astronomy observations. If the phase evolution of the THz wave keeps in step, both spatially and temporally, it is called coherent radiation. A coherent THz source is more powerful and useful in spectroscopy, material characterization, imaging, and many other applications. It is clear that a coherent polarization source is first required for generation of a coherent THz wave. In practice, the working media for THz emitting can be free electrons, quasi-free electrons in solids, or bound electrons and other charge oscillations, such as plasmon oscillation, lattice vibration, etc. Classified by the excitation properties, the emitting process can be of resonance or nonresonance. Coherent polarization sources with different features can be created using various excitation techniques under different principles and device configurations, which lead to different coherent THz sources. Here we focus on coherent THz sources, primarily based on photonic techniques, and working in the spectral range from 1 THz to a few THz.

Gas THz Laser

Molecules have many rotational and vibrational energy levels spaced at THz frequency. For polar molecules, the radiative transition between these levels can radiate THz wave. Following the standard laser technology, molecules pumped either optically or electronically can be used as laser gain media for coherent THz wave generation. For THz gas lasers, the very low THz photon energy poses a problem for lasing, because the coherent radiative transition can be disrupted by thermal depopulation and dephasing. An effective population inversion is difficult to set up and maintain. Therefore, it is important to carefully choose working medium and energy levels, as well as the way to excite the molecules. A number of media has been used for THz laser, such as methanol and HCN vapor, working in both continuous wave (CW) and pulsed modes. For example, methanol lasers operate under excitation of the rocking and asymmetric deformation modes of methanol excited by a CO_2 infrared laser. HCN laser is pumped electrically, which needs a large voltage and current to excite the molecules, a long cavity to obtain sufficient gain, and dedicated control of the temperature in the cavity for stable operation.

In general, THz gas lasers can be tuned discretely in thousands of lasing lines, ranging from a few tens to a few hundreds of micrometers, with power output from μW to mW. THz gas lasers have existed since the early 1970s, and are the only commercialized THz lasers to date. They are still subject to development, for less bulky volume, enhanced tunability and efficiency, and reduced costs.

Free Electron THz Laser

A free electron laser (FEL) uses free electrons as working medium, rather than bound atomic or molecular states in a conventional laser. A typical FEL consists of three parts: (i) an electron source that generates an electron beam with high current; (ii) an accelerator to raise the electron energy; and (iii) a lasing cavity. After the electron beam is generated, electrons are first accelerated to a relativistic velocity, typically with energy of hundreds of MeV, and then enter the cavity consisting of end mirrors and a spatially periodic magnets array called a wiggler (**Figure 2**). Due to the Lorentzean force imposed by the periodic magnetic field, the high-energy electrons move in the cavity along a sinusoidal path, and emit coherent radiation with a wavelength determined by the spacing between magnets and the electron velocity, as well as the magnetic induction. With the feedback provided by the cavity mirrors, electrons are accelerated or decelerated continuously by the optical field, and are bunched via the resonant interaction. The collective motion of the electron bunches radiates powerful coherent synchrotron radiation. In a standard configuration, the wavelength of the radiation can be expressed as:

$$\lambda = \frac{\Lambda}{2\gamma^2}[1 + (k\Lambda B_0)^2/2] \quad [3]$$

where Λ is the spatial period of the wiggler magnets, γ the Lorentz factor of the electron beam, B_0 the peak magnetic induction, and k a constant. With a suitable

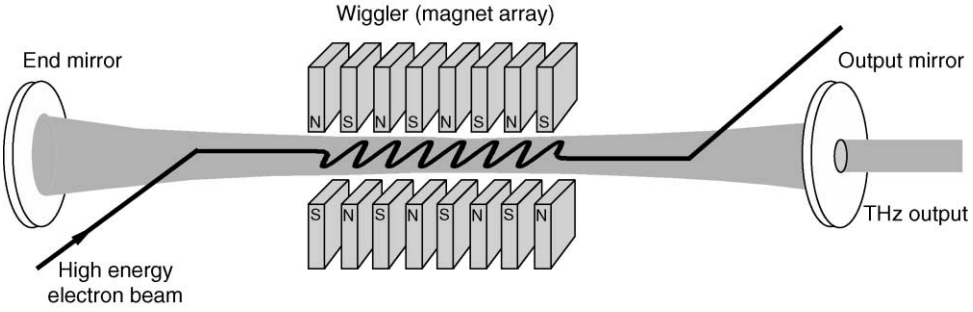

Figure 2 A schematic of THz generation in a free electron laser.

arrangement of the magnet array, as well as other related factors, the facility can work in THz spectral region.

An FEL generates tunable, coherent, high-power THz radiation. It is the most powerful coherent source of THz radiation available. Up to 50 W of average THz power has been generated in the Jefferson Lab recently. The free electron THz laser is becoming an important tools for studying THz radiation and its interactions with condensed matter and biological materials. On the other hand, the FEL is a complicated and expensive facility, and needs dedicated maintenance.

Semiconductor THz Laser

In the twentieth century, semiconductor devices have achieved tremendous success, both in electronic and photonic regime, such as transistors and diode lasers. The semiconductor industry has resulted in revolutionary changes to our world and everyday life. To fill the THz gap between electronics and photonics, great efforts have been made to meet the demand in compact, economic, tunable, and highly efficient THz sources. Encouraging advances have been made since we stepped into the new millennium.

In a semiconductor quantum well, the energy difference between a pair of sublevels can be artificially designed at THz frequency. As early as 1971, the concept of far infrared lasers based on intersub-band transition in semiconductor superlattices was proposed. Although the sublevels can be populated by electrical or optical pumping, the low photon energy at THz frequency causes serious difficulties for lasing, because the two levels sit so close to each other that many thermal processes could destroy the population inversion. Various designs and configurations have been proposed to tackle the problem. An attractive idea is so-called quantum cascade heterostructure. In this kind of device, the electrons are injected into a series of coupled quantum wells electrically. When the electrons are driven by the biased voltage, they can make radiative transition between a pair of sub-bands in a well. Subsequently, electrons enter the next well through resonant tunneling, and so on. However, this kind of device needs the materials of very high quality and suffers severely from fast depopulation of the excited states, even at very low temperatures.

As the advance in material science and unremitting efforts in pursuing the dedicated design of the device structures continued, the real breakthrough came in 2001, when Köhler *et al.* at Pisa demonstrated THz lasing in a quantum cascade heterostructure. Many improvements have been made since then; for example, the idea of using phonon resonance to selectively deplete the population of the lower sub-band has been successful, so that much stabler and robuster population inversion can be set up. The operation temperature has been raised to 136 K, well above the liquid nitrogen temperature, which opens the way for semiconductor THz lasers stepping into many more daily applications. These semiconductor devices are pumped with low voltages and currents at mA levels, and generate narrow bandwidth radiation with mW output at a frequency of a few THz. It is also probable that a four-level lasing system could even working at room temperature.

Another promising device is the p-germanium (Ge) laser developed recently. The Ge laser operates through the electrical excitation of hot holes in p-doped Ge. The laser cavity is formed by polishing the surfaces of the Ge crystal. These lasers could run at 5% duty cycles, with several mW output power. The output wavelength can be continuously tuned from 1 to 4 THz. At the moment, the devices have to operate at 20–30 K and consume about 10–20 W for refrigeration.

It is safe to predict that the feasibility, low cost, and compact semiconductor THz laser will emerge in the near future.

Beside the THz lasers, coherent THz radiation can also be generated by coherently exciting suitable media in other ways. Since the mid-1990s, the

development of ultrafast laser techniques has led to two important pulsed coherent THz sources, i.e., photoconductive antenna and optical rectification THz sources. A unique feature of the pulsed coherent sources is broad bandwidth, which is useful in spectroscopic applications. Figure 3 is a typical setup for pulsed THz generation and spectroscopic study, using photoconductive antenna or optical rectification as THz sources.

THz Photoconductive Antenna (PCA)

Different from a conventional antenna working in radio and microwave frequency that are driven directly by electrical current, a photoconductive antenna for THz wave generation works with ultrafast pulsed lasers. When the photoconductive gap is irradiated by an ultrafast laser pulse, photocarriers are generated in the semiconductor. These photocarriers are driven by a DC voltage bias and form a current transient. The antenna couples the electromagnetic field associated with the time varying current into free space, and produces a THz pulse. The THz pulse usually has a duration of a few picoseconds, with a broad frequency bandwidth centered at THz frequency. The output THz power scales with both the optical pulse power and the DC bias field:

$$E_{\mathrm{THz}} \propto \frac{\partial J}{\partial t} \propto \frac{\partial^2 n_{\mathrm{e}}}{\partial t^2} E_{\mathrm{bias}} \qquad [4]$$

The output power, frequency bandwidth, and polarization of the THz radiation depend on the photoconductive features of the semiconductor layer and the geometric structure of the antenna. For an optimal performance, the substrate should have a suitable bandgap for optical interband excitation, a high electron mobility and short carrier lifetime to support an ultrafast current transient, and high dielectric breakdown threshold and to sustain high bias voltage. High-power PCAs have been demonstrated with semi-insulating GaAs, ion-implanted GaAs, and In-GaAs. In the aspects of antenna structures, coplanar strip lines and large aperture emitters are the most effective. Average output power from a good system can reach 30–40 μW.

A broad bandwidth is a special characteristic of a THz source, which is particularly desirable in the spectroscopic study as a coherent probe source. From the property of Fourier transform, we know that the shorter the THz pulse duration, the broader the spectral band. PCAs made of GaAs typically have a useful bandwidth extending from ~100 GHz to 3 THz, which can be extended to 4 THz by tuning the pumping laser wavelength close to the bandedge. Up to 6 THz bandwidths have been reported for PCAs. The pulse duration and, therefore the achievable bandwidth, are ultimately limited by carrier mobility and TO phonon resonant absorption which is around 8.3 THz in GaAs.

In many applications, THz radiation is coupled to free space from the antenna using a closely attached silicon hemispherical lens. This practice increases the system's output and also provides control of the radiation pattern. The radiation pattern for the common dipole antenna is essentially dipolar, with a weak quadrupole component perpendicular to the bias field. In the far-field, the THz beam has a Gaussian cross-section with high-frequency components concentrated in the center.

As the first practical pulsed coherent THz source, PCA has been widely used for many applications in

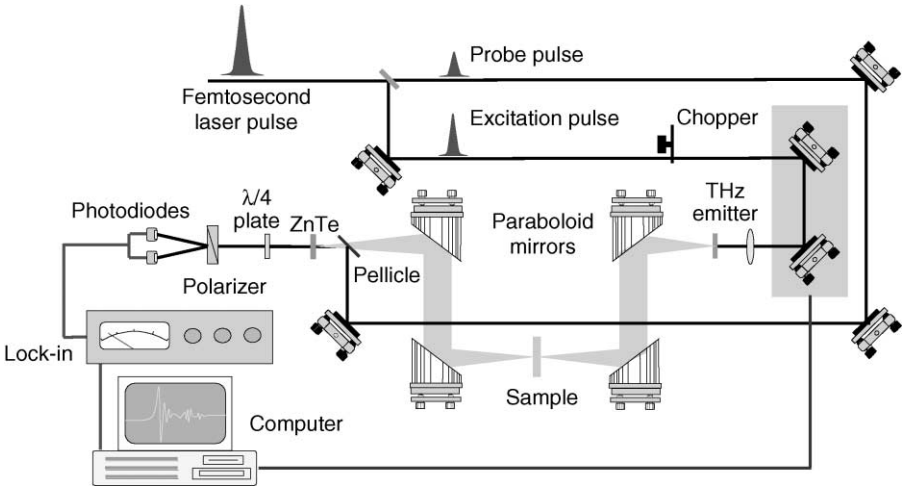

Figure 3 A typical setup for broadband pulsed THz generation and spectroscopic study with a femtosecond laser as excitation source.

scientific research and material characterization. Combined with commercial ultrafast optical fiber lasers, full functional and self-contained THz spectroscopy systems with PCAs as emitters, have been demonstrated and are under commercialization.

Optical Rectification

Optical rectification is a second-order nonlinear optical effect originating from susceptibility $\chi^{(2)}$, and was first observed in 1962 using two intense monochromatic nanosecond laser pulses. In this process, the interaction between laser and nonlinear optical crystal produces a frequency difference polarization:

$$P(0) = \chi^{(2)} E(\omega_1) E(-\omega_1) \qquad [5]$$

When a nonlinear optical crystal is irradiated by an ultrafast laser pulse, the different frequency components in the laser pulse will be coupled with each other by $\chi^{(2)}$, to induce frequency difference polarizations as:

$$P(\Omega) = \chi^{(2)}(\omega_1 - \omega_2 = \Omega) E(\omega_1) E(-\omega_2) \qquad [6]$$

A femtosecond laser pulse usually has a spectral linewidth of at least a few nm, the induced polarization $P(\Omega)$ has a finite frequency distribution centered at THz frequency in the far field, and results in THz radiation $E_{\mathrm{THz}} \propto \partial^2 P(t)/\partial t^2$.

THz radiation in free space by optical rectification was obtained in the early 1990s. One of the differences from a PCA device is that the THz output by optical rectification scales with both the optical pulse power and the DC bias field, while the THz radiation generated by optical rectification solely results from the incident laser. The optimal performance depends on several factors. The generation efficiency first depends on the magnitude of the $\chi^{(2)}$ and phase-matching condition between the optical and THz pulses. The effective magnitude of the $\chi^{(2)}$ coefficient varies with the crystal cut and orientation. Up to now, the most popular material is ZnTe, for its physical durability and excellent phase matching, when a Ti:sapphire femtosecond laser is used as the excitation source. With a moderately focused optical pump beam and a ZnTe crystal, nW T-ray average power can be generated by optical rectification. In general, the generation efficiency may be increased by increasing the laser power, but there are two factors limiting the effect. First, the incident laser power cannot exceed the damage threshold. Second, other second-order nonlinear processes may compete with the optical rectification, such as second-harmonic generation of the pump beam at high optical flux.

For THz radiation generated by optical rectification, the ultimate bandwidth is primarily determined only by the linewidth of the pump laser pulse. Because it is a nonresonance process in most cases, optical rectification can reach broader bandwidths than PCA. Using ultrashort optical pulses and thin nonlinear crystal, THz pulses have been generated with spectra extending to the mid-infrared, well beyond the phonon band of the materials. Like the photoconductive antenna, optical rectification has become a popular technique to generate coherent broadband THz radiation in various applications. Beside the conventional bulk inorganic crystals, many different media have been used for THz generation, such as organic crystal DAST, biased quantum wells, periodically poled LiNbO3 (PPLN), poled polymers, super-conducting thin films, etc.

Other Coherent THz Sources

When two light sources with slightly different wavelengths interact together with a nonlinear optical crystal, a beating polarization will be generated and will radiate a THz wave. It is called difference frequency generation, or three-wave mixing. Optical parametric processing is another way to generate a THz wave. In this process, a near-infrared pump beam generates a second NIR idler beam in a nonlinear crystal, and THz radiation can be generated from the beating of the pump and the idler. The merit of this technique is the continuous frequency tunability of the THz output, which is valuable in spectroscopic applications, and relatively cheaper nanosecond lasers can be used. If the nonlinear crystal is further placed in a cavity and the idler beam is amplified by feedback from end mirrors, a THz optical parametric oscillator is formed. A number of improvements have been made since the mid-1990s with this kind of device. More recently, THz parametric generation with an injection seeded idler beam has shown a reduced linewidth ($\Delta\nu/\nu \approx 10^{-4}$) and a peak THz power of over 100 mW for 3.4 ns pulses. A narrow linewidth combined with reasonable tunability make this kind of THz source attractive in spectroscopic studies.

Besides using photonic techniques, coherent THz radiation can also be generated by electronic techniques through increasing the output frequency of the microwave devices. For example, an electrically driven microwave generator, backward wave oscillator, can generate CW THz radiation up to 2 THz. A backward wave oscillator, running under optimal conditions, can provide up to 300 mW of polarized, narrowband radiation with a limited tunability about 30% of its central frequency.

Introduction

The terahertz (THz) regime of the electromagnetic spectrum holds promise for a large number of important applications in areas like environmental sensing, quality control, medicine, military applications, astronomy, etc. The development of THz devices has been mainly hindered by the lack of compact sources. In this article we overview the types of tabletop semiconductor sources that are available right now. We focus on the use of pulsed THz sources that are optically excited by femtosecond laser pulses. The generated bursts of THz radiation are extremely useful for time-resolved THz spectroscopy of semiconductor heterostructures.

THz Generation from Semiconductors

The first freely propagating THz pulses using femtosecond lasers were generated in 1984 when Auston *et al.* fabricated a Hertzian dipole antenna. It mainly consists of an electrically biased transmission line structure mounted on a semiconductor, i.e. a photoconductive switch that is triggered by a femtosecond laser pulse (Figure 1). The generated transient photocurrent $J(t)$ emits radiation according to $E(t) \propto \partial J(t)/\partial t$. Since 1989, sapphire half-spheres or refractive silicon lenses have been attached to these dipole antennas, which made it possible to produce collimated THz beams for use in everyday spectroscopic experiments. Today generation and detection of THz radiation by semiconductor photoconductive antennas is widely used. However, most of the antennas are limited to the low-frequency regime of the THz spectrum since they usually have a high-frequency cutoff of about 1–2 THz.

THz generation from semiconductor surfaces was introduced by Zhang in 1990. There are three different physical mechanisms that are responsible for the surface emission of THz radiation. One is the transient current, i.e., the acceleration of photogenerated carriers in the semiconductor surface electric field. This process is accompanied by field induced optical rectification which is often called instantaneous polarization, where the electron–hole pairs are polarized in the dc electric field. Finally, bulk optical rectification as a source of THz radiation can be observed in noncentrosymmetric crystals.

The surface emission intensity can be enhanced by using an externally applied electric field instead of the intrinsic electric field. Until recently, the use of laser amplifiers that optically pump these so-called large-aperture antennas has led to the brightest ultrafast tabletop THz emitters.

Recently, Sarukura and co-workers found that the application of a magnetic field dramatically increases the THz emission from bulk InAs. This led to a re-examination of Zhang's work, in which he reported the magnetic field enhancement in bulk GaAs,

Copyright (1992) by the American Physical Society.

and to a large number of studies of different types of other semiconductors in various magnetic field geometries. Currently, there is no unified model of the enhancement mechanism(s).

The use of a semiconductor heterostructure by Roskos *et al.* in 1992 (a coupled double quantum well) marked the advent of a new class of semiconductor THz emitters that can be deliberately designed using bandgap engineering. In these devices the quantum nature of electrons in coupled potential wells is used to generate electron wavepackets that tunnel back and forth between different potential wells (Figure 2). The coherent charge oscillation is triggered by a femtosecond laser pulse that has a spectral width that is larger than the separation between the quantized states in the well. In this way a coherent superposition of these levels is created. THz emission from these quantum beats has also been observed from charge oscillations due to light and heavy hole excitons in a quantum well by Planken and co-workers. The concept of quantum beats can even be transferred to the high-THz regime (tens of THz) which was successfully demonstrated by Bonvalet and co-workers. By using an InAs step quantum well they generated THz radiation at a frequency of 30 THz.

Bloch oscillations, one of the fundamental concepts of solid state physics, were predicted in 1934 by Zener. He stated that electrons in a periodic potential under an applied electric field should perform oscillations. Using a quantum mechanical picture, Bloch oscillations can be described as a quantum beat of Wannier–Stark states and in 1993 Waschke *et al.* detected THz emission from these oscillations.

These heterostructure THz sources are inherently frequency tunable since the energy level spacing can be altered by an applied electric field that tilts the quantum wells. The Bloch frequency is given by:

$$\omega_{\text{Bloch}} = \frac{eFd}{\hbar} \qquad [1]$$

where F is the applied electric field and d is the superlattice period. Unfortunately, these devices suffer from their low emission power.

An alternative concept is the use of collective excitations in semiconductor bulk material or heterostructures. Dekorsy and co-workers showed in 1995 that coherent phonons emit THz radiation when excited by femtosecond laser pulses. In the same year Sha and co-workers studied the absorption changes within an electrically biased GaAs p-i-n structure and found distinct oscillations which they ascribed to another collective phenomenon, namely coherent plasma oscillations of the photogenerated carriers (Figure 3). This explanation was supported by the square-root dependence of the observed frequencies on the photogenerated carrier density which is predicted by a simple oscillator model:

$$\omega_{\text{p}} = \sqrt{\frac{ne^2}{\varepsilon\varepsilon_0 m^*}} \qquad [2]$$

where n is the carrier density, ε the dielectric constant, and m^* the effective mass of the carriers. Fischler and co-workers confirmed this finding and in particular investigated the damping behavior of the plasmons. In 1997, Kersting *et al.* detected THz radiation from

these p-i-n structures and identified heating of the photogenerated carriers as the origin for the strong damping of the plasma oscillations resulting in a low emission intensity.

This problem can be circumvented by using coherent plasma oscillations of extrinsic charge carriers. These electrons are cold compared to the photo-excited carriers and should undergo less scattering. Kersting *et al.* showed that THz pulses are indeed emitted from coherent three-dimensional (3D) plasma oscillations in n-doped GaAs epilayers. The THz pulses are temporally and spatially coherent with intensities up to 100 nW.

Figure 4 shows the THz emission from three GaAs epilayer samples which have been doped with densities 1.9×10^{15}, 1.7×10^{16}, and $1.1 \times 10^{17}\,\mathrm{cm}^{-3}$. The curves are recorded using an autocorrelation technique: 13 nJ, 100 fs laser pulses at a repetition rate of 80 MHz and a central wavelength of 800 nm are split into two pulses with a Michelson interferometer. Every visible pulse generates a THz pulse in the transmission or pseudo-reflection direction. After collimating and focusing of the THz radiation by parabolic mirrors, the interference of the two THz pulses can be recorded by changing the time delay between the visible pulses (Figure 5). Assuming negligible nonlinear interactions between the two excitation processes, the linear autocorrelation function can be recorded. The spectrum is calculated by simply Fourier transforming (Figure 4b). The experiments are performed at room temperature, and the whole setup is purged with dry nitrogen gas to prevent

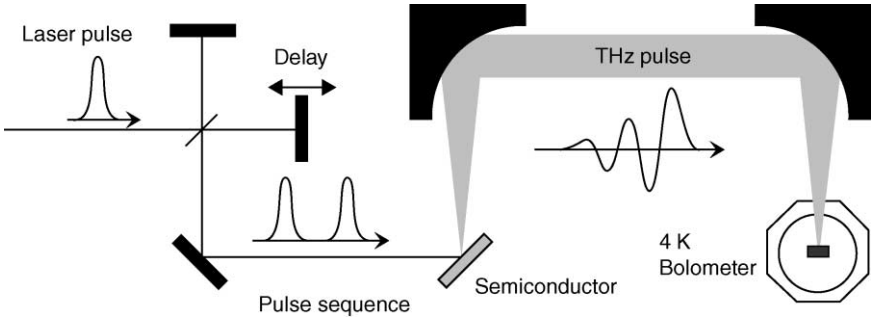

Figure 5 THz autocorrelation setup. Reproduced with permission from Kersting R, Heyman J, Strasser G and Unterrainer K (1998) Coherent plasmons in n-doped GaAs. *Physical Reviews B* 58: 4553. Copyright (1998) by the American Physical Society.

water vapor absorption. Although the autocorrelation traces are recorded at the same optical excitation density of $n_{ex} = 2 \times 10^{16}$ cm^{-3}, the emission frequency changes significantly. In addition, the autocorrelation trace of the highly doped structure (1.1×10^{17} cm^{-3}) shows multiple oscillations while in the case of the sample with the lowest doping (1.9×10^{15} cm^{-3}) the slow oscillation is damped out rather quickly. The frequency behavior of the three different samples can be analyzed from the spectra shown in Figure 4b. The bars indicate the frequency calculated with [2] and setting n equal to the doping density determined by standard Hall measurements. Obviously, the calculated frequencies match very well the experimentally determined ones. This indicates that the THz emission results from a collective oscillation of the extrinsic electrons within the epilayer. This is also supported by the observation that a variation of the excitation density of the photogenerated carriers over two orders of magnitude does not change the THz emission frequency. This is in clear contrast to the experiments with undoped semiconductors where the emission frequency shows a square-root dependence on the optically excited carrier density.

Excitation of the coherent plasma oscillation results from the ultrafast screening of the surface electric field by the femtosecond laser pulse. Before excitation, the doping electrons are confined between the surface electric field and the undoped GaAs substrate (Figure 6). A short laser pulse with an energy above the bandgap of the semiconductor generates electron–hole pairs that screen this surface electric field for a short time. The doping electrons inside the material respond to the change in potential at the surface of the sample leading to the oscillation behavior. A detailed model calculation of the excitation mechanism can be found in Kersting *et al.* (1998). The oscillation frequency – the eigenfrequency of the electron system – is simply the plasma frequency given by the simple formula [2].

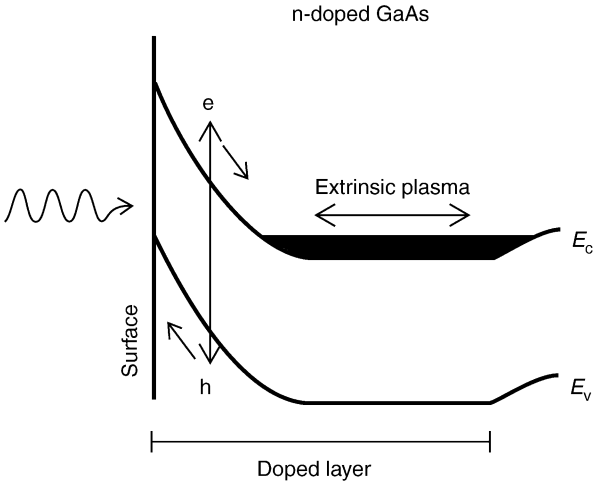

Figure 6 Schematic drawing of the 3D plasmon excitation. After Kersting R, Bratschitsch R, Heyman JN and Unterrainer K (1999) Unpublished.

There are two mechanisms that are responsible for the damping of the plasma oscillations. If the doping density is lower than 10^{16} cm^{-3} the coherence time of the 3D plasmon is mainly limited by optical phonon scattering. This can be verified by measuring the plasmon damping times at different temperatures and comparing the results with mobility data which show the same tendency. Since optical phonon scattering is suppressed at low temperatures, the THz emission intensity can be substantially increased by cooling the sample. In the high-doping-density regime $>10^{16}$ cm^{-3} the observed damping times are shorter than those expected due to the optical phonon scattering mechanism alone. This is because in this regime impurity scattering is the dominant scattering mechanism.

One way around this problem is the use of a remotely doped structure. In this case the scatterers are not in the same region as the electrons that perform the plasma oscillation (Figure 7). The higher mobility should lead to a longer decoherence time.

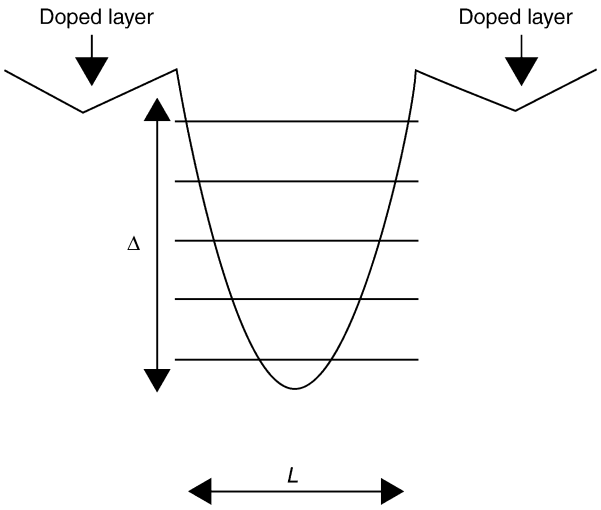

Figure 7 Schematic drawing of a modulation-doped PQW. The doped layers are outside the quantum well.

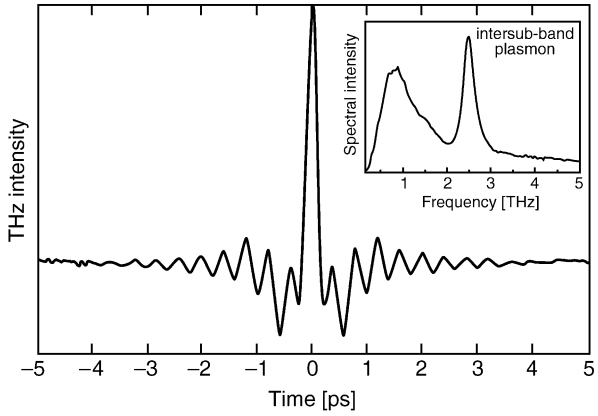

Figure 8 THz autocorrelation signal of a 1400 Å PQW excited by 780 nm laser pulses ($T = 5$ K). Inset: Fourier transform of the recorded autocorrelation. Reproduced with permission from Bratschitsch R, Müller T, Kersting R, Strasser G and Unterrainer K (2000) Coherent THz emission from optically pumped intersubband plasmons in parabolic quantum wells. In: *Ultrafast phenomena XII*. Springer series in Chemical Physics, vol. 66, pp. 204. New York: Springer-Verlag.

For this purpose Bratschitsch *et al.* used modulation doped GaAs/AlGaAs parabolic quantum wells (PQWs), with widths L in the range of 1200–2000 Å and carrier sheet densities n_s of $1.7 \times 10^{11} - 5 \times 10^{11}$ cm^{-2}. The electrons confined within the parabolic potential form a so-called quasi-3D electron system. Figure 8 shows the THz autocorrelation trace of a modulation doped PQW ($L = 1400$ Å, $n_s = 5 \times 10^{11}$ cm^{-2}) excited by 780 nm laser pulses. The density of the optically generated carriers is kept well below the carrier density due to the modulation doping inside the PQW.

The spectrum of the emitted THz radiation (inset of Figure 8) consists of two components: a broad background and a narrow line (FWHM: 0.3 THz) with a center frequency of 2.55 THz. The low-frequency broadband component is found for all the different PQW samples and is independent of the PQW sample structure. It can also be observed at room temperature while the narrowband component completely vanishes. The origin of the broadband component is due to THz generation at the surface of the sample.

The THz emission at 2.55 THz can be observed within a wide range of excitation wavelengths (815–760 nm) above the 819 nm GaAs bandgap ($T = 5$ K). When varying the excitation density over one order of magnitude ($5.6 \times 10^{10} - 6.2 \times 10^{11}$ cm^{-2}), the emission frequency does not change. The narrowband emission results from the oscillation of the carriers inside the PQW. The observed frequency corresponds to the intersub-band plasmon of the PQW. The expected frequency of the intersub-band plasmon is given by

$$\omega_0 = \sqrt{\frac{8\Delta}{L^2 m^*}} \qquad [3]$$

where Δ is the energetic depth of the well, L is the well width, and m^* the effective mass. For the 1400 Å wide PQW the formula yields 2.2 THz for the intersubband plasmon frequency.

The excitation mechanism for the intersub-band plasmon is due to screening of the surface depletion field by the electron–hole pairs injected by the ultrafast laser pulse. In this way the electrons inside the quantum well experience a kick and begin to oscillate with their eigenfrequency (Figure 9). This is supported by the fact that the oscillation can be excited over a large wavelength range of the femtosecond pulses. The onset of intersub-band plasmon emission appears at 815 nm near the 819 nm GaAs bandgap ($T = 5$ K) and can be observed to up to 760 nm. This large range implies that the excitation mechanism is clearly a nonresonant phenomenon, in contrast to the THz quantum beat experiments. Due to ultrafast field screening, a symmetric nanostructure can emit optically driven THz radiation.

The width of the intersub-band plasmon emission line is 0.3 THz (full width at half maximum; FWHM) for the 1400 Å PQW and even 0.2 THz for the 2000 Å PQW sample. The linewidth is a factor of 5 smaller than the smallest linewidth measured for a 3D plasmon emitter. The width of the intersub-band emission is nearly unaffected when increasing the excitation wavelength from near bandgap to approximately 60 nm above bandgap. However, it shows a linear dependence ($5.6 \times 10^{10} - 6.2 \times 10^{11}$ cm^{-2}) on

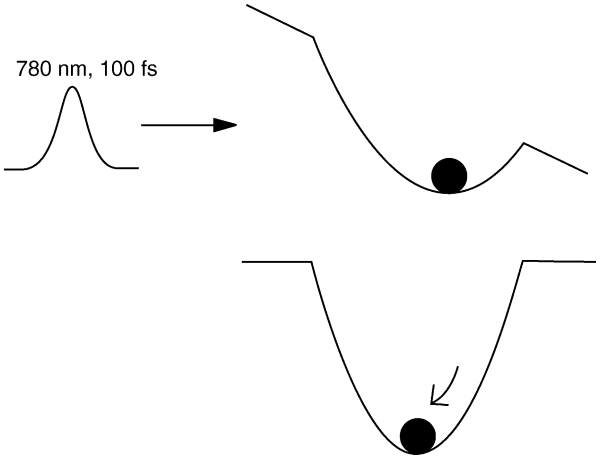

Figure 9 Symbolic drawing of the excitation mechanism: an oscillation of the carriers in the parabolic potential is initiated by ultrafast field screening. Reproduced from Bratschitsch R, Müller T, Kersting R, Strasser G and Unterrainer K (2000) Coherent terahertz emission from optically pumped intersubband plasmons in parabolic quantum wells. *Applied Physics Letters* 76: 3501, with permission from the American Institute of Physics.

the number of optically excited carriers. These optically injected carriers are added to those from the modulation doping and cause a faster dephasing of the intersubband plasmon oscillation. This linear dependence due to carrier–carrier scattering has also been observed in Wolter's experiments dealing with the dephasing of Bloch oscillations in semiconductor superlattices. The linewidth stays constant up to about 50 K (0.33 THz = 1.36 meV) and then starts to broaden until the sample temperature reaches 150 K where the PQW emission is buried by the surface-generated THz emission. The broadening of the line between $T = 50$ K and $T = 150$ K can be explained by the onset of optical phonon scattering in addition to interface roughness scattering which is the dominant scattering mechanism at low temperatures. The onset and linear increase of the line broadening has also been observed with Fourier Transform Infrared (FTIR) absorption and THz time-domain cross-correlation spectroscopy measurements by Kersting and co-workers.

The combination of the designability of the transition frequency, the narrowband emission, and the absence of any processing of the sample make modulation-doped PQWs attractive and easy-to-use THz emitters.

Other THz emission experiments of heterostructures include the optically pumped emission of THz radiation from grating-coupled intrasub-band (2D) plasmons in a doped single quantum well observed by Sekine and co-workers or optically excited THz emission from coherent plasmons in doped superlattices detected by Bratschitsch and co-workers.

Few-Cycle THz Spectroscopy of Semiconductor Quantum Structures

There are a large number of studies that use few-cycle THz radiation for the investigation of semiconductor bulk materials. The complex index of refraction in the THz regime gives insight into the conductivity (i.e., carrier mobility) of the material. The free carriers that change the index of refraction by Drude absorption can be provided either by doping (n-doped silicon or GaAs) or by photo-excitation. An optical pump-THz probe experiment with undoped GaAs reveals the different intervalley scattering times.

There are compelling reasons to use THz radiation to excite and probe carriers in semiconductor quantum structures. The photon energies are comparable to the sub-band spacings, carrier kinetic energies, and phonon energies. In addition, THz radiation does not generate minority carriers so that the experiments directly probe free carriers rather than excitons.

Heyman *et al.* investigated a modulation-doped GaAs/AlGaAs multiple quantum well ($d = 510$ Å, 10×) with a transition energy between the two lowest sub-bands of 1.5 THz and a carrier density of $n_s = 2.75 \times 10^{10}$ cm^{-2}. On top of the sample an aluminum Schottky gate is evaporated and the well is contacted with AuGe alloyed ohmic contacts. The wells can be depleted of carriers by applying a negative gate voltage to the Schottky gate (−10 V gate bias). By modulating the voltage between 0 V and −10 V the response of the 2D electron system can be measured. Otherwise, the recorded signal is dominated by the contribution of the bulk GaAs substrate that dramatically chirps the THz pulse due to its frequency-dependent index of refraction. The THz pulses are coupled into the cleaved edge of the quantum well sample so that the electric field is parallel to the growth direction in order to excite the intersub-band transition. The electrons' response is measured with a cross-correlation technique. Here the THz radiation transmitted through the quantum well is mixed with a short THz pulse emitted from low-temperature grown GaAs to get the desired time resolution in the experiment. This allows the detection of the transmitted signal in amplitude and phase. Figure 10 shows the cross-correlation signal of the QW. The signal from the carriers rises during the first 2 ps in response to the THz field and then continues to oscillate at a constant frequency of 1.5 THz. Due to the femtosecond time resolution in this experiment it is possible to observe the phase of the electrons even during the process of excitation. Initially, the incident THz pulse generates a coherent superposition of states in the first and second sub-band. After the THz driving pulse is over

(>2 ps) the carriers continue to radiate at the intersub-band transition frequency, and the signal is damped out by the free induction decay. Since the amplitude and phase of the radiated electric field is recorded, not only the absorption due to the QW electrons but also the phase shift associated with the absorption can be extracted (Figure 11).

This experiment showed the response of the QW electrons to radiation which is resonant to the intersub-band transition. Using the same experimental technique Kersting *et al.* investigated the response of electrons to a non-resonant excitation of the intersub-band transition. Instead of a square QW, a modulation-doped parabolic quantum well is used in this experiment which has the advantage that the transition frequency is independent of the carrier concentration (Kohn's theorem) and the applied electric field. Furthermore the THz radiation is coupled to the intersub-band transition via a metallic Schottky grating. Figure 12 shows the response of the QW electrons to resonant THz radiation. The electrons follow the driving pulse and continue to radiate at the intersub-band transition frequency. The response to a nonresonant THz pulse is shown in Figure 13. Initially, the electrons inside the QW follow the driving pulse but when the driving pulse has ended a phase jump occurs and the electrons lock to their eigenfrequency and slowly lose their coherence. This behavior can be understood by using time-dependent perturbation theory to solve Schrödinger's

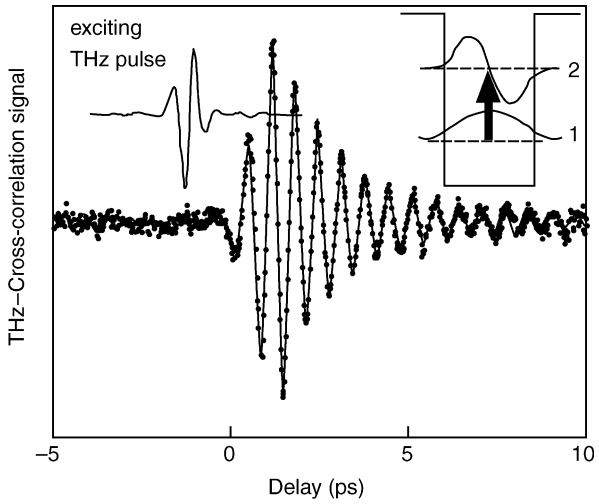

Figure 10 Cross-correlation signal obtained by electrically modulating the charge density in a 510 Å wide quantum well. The THz pulse generates a coherent superposition of the $n = 1$ and $n = 2$ sub-band states. The resulting oscillating polarization radiates and is damped out by the free induction decay. The upper trace shows the incident THz pulse. equation for a two-level system with an electromagnetic driving field. While the two-level system is treated quantummechanically, the dipole Hamiltonian is used for the incoming THz radiation: $H = H^0 + H'(t)$ and $H'(t) = \mu E(t)$. Making the ansatz $\Psi(t) = a_1(t)\Psi_1 + a_2(t)\Psi_2$ one gets a system of two coupled equations for $a_1(t)$ and $a_2(t)$. They can be decoupled by the condition that the population in the lower level is close to one ($\left\|a_1^2\right\| \approx 1$) since the THz radiation field is not very strong. Figure 14 shows the result of the model calculation that reproduces the change in frequency as well as the observed phase jump after the driving pulse is over.

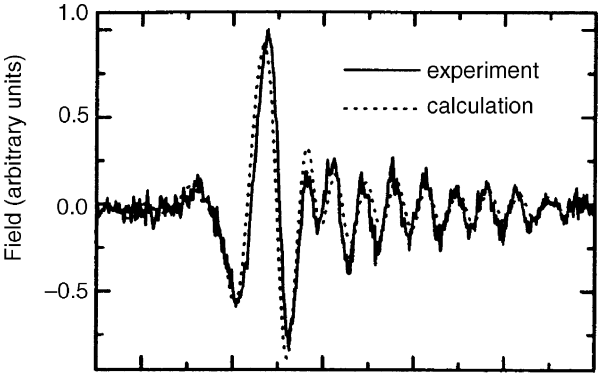

Figure 14 Model calculation of the polarization (dotted curve) and experimental data (solid line). These experiments are all performed in the linear regime but with nonadiabatic excitation conditions (half-cycle THz pulses). The excellent time resolution together with sufficiently high THz intensities can open up a previously unexplored field of quantum optics beyond the slowly varying envelope approximation.

Conclusions

The recent progress in the development of semiconductor sources together with room temperature THz detection techniques (free-space electro-optic sampling) paves the way for the commercialization of THz technology. In particular, spectrally sensitive THz imaging seems to have great potential in medicine and quality control of products.

Introduction

Fluorescence is extensively used in physical, chemical, material, biological, and medical sciences, for investigating the structure and dynamics of matter or living systems. After excitation of a fluorescent sample by a short pulse of light, the fluorescence decay is, in the simplest case, a single exponential whose time constant is the lifetime of the excited state of the fluorescent species (i.e., the average time during which these species stay in the excited state). However, interactions of a fluorescent species with its micro-environment often perturb the fluorescence decay so that information on this micro-environment can be obtained. More specifically, when intermolecular photophysical processes

(such as electron transfer, proton transfer, energy transfer, excimer, or exciplex formation) occur during the lifetime of the excited state, competition with normal de-excitation results in a fluorescence decay that contains the rate constants for those processes. Consequently, the fluorescence decay is generally a sum of discrete exponentials, or a more complicated function; for example, sometimes the system is characterized by a distribution of decay times. Thus it is of major interest to recover the parameters characterizing the δ-pulse response of a fluorescent sample (i.e., the response to an iznfinitely short pulse of light expressed as the Dirac function δ). With this aim, two time-resolved techniques, pulse fluorometry and phase-modulation fluorometry, are usually employed.

In pulse fluorometry, the sample is excited by a short pulse of light, and the fluorescence response is the δ-pulse response of the sample convoluted by the instrument response. In phase-modulation fluorometry, the sample is excited by modulated light at variable frequency, and the harmonic response of the sample obtained is the Fourier transform of the δ-pulse response. The first technique works in the time domain, and the second technique in the frequency domain. Pulse fluorometry and phase-modulation fluorometry are theoretically equivalent, but the principles of instrumentation are different. In both techniques, lasers are currently used as sources of pulsed or modulated light.

It is the aim of this article to explain the principles of pulse and phase fluorometries using lasers as light sources, and to compare these techniques.

General Principles of Time-Resolved Fluorometry

The principles of time-resolved fluorometry are illustrated in Figure 1. For any excitation function $E(t)$, the fluorescence response $R(t)$ of the sample is the convolution product of this function by the δ-pulse response $I(t)$:

$$R(t) = E(t) \otimes I(t) = \int_{-\infty}^{t} E(t')I(t - t')\,dt' \qquad [1]$$

In pulse fluorometry, the sample is excited by a short pulse of light and the fluorescence response is recorded as a function of time. If the duration of the pulse is not short with respect to the time constants of the fluorescence decay, the fluorescence response is the convolution product given by eqn [1]: the fluorescence intensity increases, goes through a maximum, and becomes identical to the true δ-pulse response $i(t)$ as soon as the intensity of the light pulse becomes negligible. In this case, data analysis for the determination of the parameters characterizing the δ-pulse response requires deconvolution of the fluorescence response.

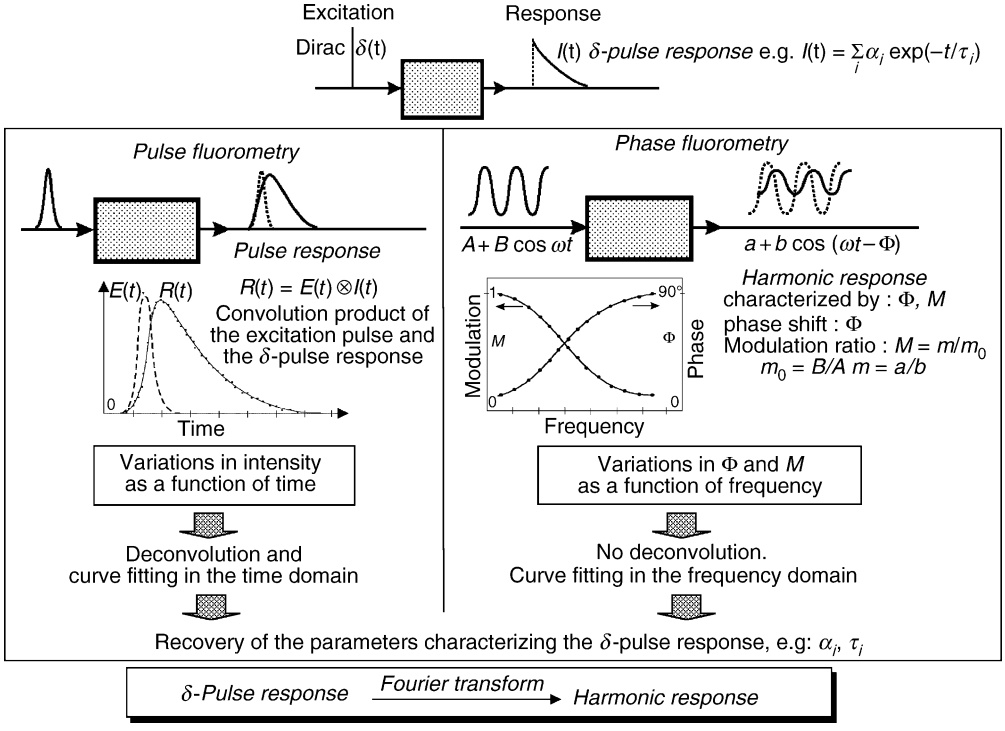

Figure 1 Principles of time-resolved fluorometry.

In phase fluorometry, the sample is excited by a sinusoidally modulated light at high frequency. The fluorescence response, which is the convolution product (eqn [1]) of the δ-pulse response by the excitation function, is sinusoidally modulated at the same frequency, but delayed in phase and partially demodulated with respect to the excitation. The modulation ratio M is defined as the ratio of the modulation depth m (AC/DC ratio) of the fluorescence and the modulation depth of the excitation m_0 (see **Figure 1**). The phase shift Φ and the modulation ratio M characterize the harmonic response of the system. These parameters are measured as a function of the modulation frequency. No deconvolution is necessary because the data are directly analyzed in the frequency domain.

The relationship between the harmonic response and the δ-pulse response can be obtained as follows. When the excitation function is sinusoidal, i.e., of the following form:

$$E(t) = E_0[1 + m_0 \exp(\mathrm{i}\omega t)] \qquad [2]$$

where ω is the angular frequency ($= 2\pi f$), the response of the system can be calculated using eqn [1]. It can then be shown that

$$M \exp(-\mathrm{j}\Phi) = \int_0^\infty i(t) \exp(-\mathrm{i}\omega t)\, \mathrm{d}t \qquad [3]$$

where $i(t)$ is the normalized δ-pulse response according to

$$\int_0^\infty i(t)\, \mathrm{d}t = 1 \qquad [4]$$

This important expression shows that the harmonic response expressed as $M \exp(-\mathrm{j}\Phi)$ is the Fourier transform of the δ-pulse response.

It is convenient to introduce the sine and cosine transforms P and Q of the δ-pulse response:

$$P = \int_0^\infty i(t) \sin(\omega t)\, \mathrm{d}t \qquad [5]$$

$$Q = \int_0^\infty i(t) \cos(\omega t)\, \mathrm{d}t \qquad [6]$$

If the δ-pulse response is not normalized according to eqn [4], then eqns [5] and [6] should be replaced by

$$P = \frac{\int_0^\infty I(t) \sin(\omega t)\, \mathrm{d}t}{\int_0^\infty I(t)\, \mathrm{d}t} \qquad [7]$$

$$Q = \frac{\int_0^\infty I(t) \cos(\omega t)\, \mathrm{d}t}{\int_0^\infty I(t)\, \mathrm{d}t} \qquad [8]$$

Since eqn [3] can be rewritten as $M \cos \Phi - iM \times \sin \Phi = Q - iP$, it is easy to show that the phase shift and the modulation ratio are given by

$$\Phi = \tan^{-1}\left(\frac{P}{Q}\right) \qquad [9]$$

$$M = [P^2 + Q^2]^{1/2} \qquad [10]$$

For a single exponential decay, the δ-pulse response is

$$I(t) = \alpha \exp(-t/\tau) \qquad [11]$$

where τ is the decay time and α is the pre-exponential factor or amplitude. The phase shift and relative modulation are related to the decay time by

$$\tan \Phi = \omega\tau \qquad [12]$$

$$M = \frac{1}{(1 + \omega^2\tau^2)^{1/2}} \qquad [13]$$

For a multi-exponential decay with n components, the δ-pulse response is

$$I(t) = \sum_{i=1}^{n} \alpha_i \exp(-t/\tau_i) \qquad [14]$$

Note that the fractional intensity of component i, i.e., the fractional contribution of component i to the total steady-state intensity, is

$$f_i = \frac{\int_0^\infty I_i(t)\, \mathrm{d}t}{\int_0^\infty I(t)\, \mathrm{d}t} = \frac{\alpha_i\tau_i}{\sum_{i=1}^{n} \alpha_i\tau_i} \qquad [15]$$

with, of course, $\sum_{i=1}^{n} f_i = 1$.

Using eqns [7] and [8], the sine and cosine Fourier transforms, P and Q, are given by

$$P = \frac{\omega \sum_{i=1}^{n} \dfrac{\alpha_i\tau_i^2}{1 + \omega^2\tau_i^2}}{\sum_{i=1}^{n} \alpha_i\tau_i} = \omega \sum_{i=1}^{n} \frac{f_i\tau_i}{1 + \omega^2\tau_i^2} \qquad [16]$$

$$Q = \frac{\sum_{i=1}^{n} \dfrac{\alpha_i\tau_i}{1 + \omega^2\tau_i^2}}{\sum_{i=1}^{n} \alpha_i\tau_i} = \sum_{i=1}^{n} \frac{f_i}{1 + \omega^2\tau_i^2} \qquad [17]$$

It should be noted that the optimum frequency for decay time measurements using either the phase shift or the modulation ratio is, according to eqns [12] and [13], such that $\omega\tau$ is close to 1, i.e., $f \approx 1/(2\pi\tau)$. Therefore, for decay times of 10 ps, 1 ns and 100 ns, the optimum frequencies are about 16 GHz, 160 MHz and 1.6 MHz, respectively.

In the case of a single exponential decay, eqns [12] and [13] provide two independent ways of measuring the decay time:

– by phase measurements:

$$\tau_\Phi = \frac{1}{\omega}\tan\Phi \qquad [18]$$

– by modulation measurements:

$$\tau_M = \frac{1}{\omega}\left(\frac{1}{M^2} - 1\right)^{1/2} \qquad [19]$$

The values measured in these two ways should, of course, be identical and independent of the modulation frequency. This provides two criteria to check whether an instrument is correctly calibrated, by using a lifetime standard whose fluorescence decay is known to be a single exponential.

It should be noted that the measurement of a decay time is fast (a fraction of a second) for a single exponential decay since a single frequency suffices. It is also of interest that a significant difference between values obtained by means of eqns [18] and [19] is compelling evidence for nonexponentiality of the fluorescence decay.

Pulse Fluorometers

The most widely used technique in time domain is the time-correlated single-photon counting technique, preferably called single-photon timing technique (SPT). Time-gated systems are less popular. Streak cameras offer a very good time resolution (a few picoseconds or less) but the dynamic range is smaller than that of the single photon-timing technique. The instruments that provide the best time resolution (a few tens of femtoseconds) are based on fluorescence up-conversion, but they are very expensive and not commercially available. Because of space limitations, only the single-photon timing technique will be presented below.

Principle of the Single-Photon Timing Technique

The basic principle of this technique relies on the fact that the probability to detect a single photon at time t, after an exciting pulse, is proportional to the fluorescence intensity at that time. After timing and recording the single photons following a large number of exciting pulses, the decay of the fluorescence intensity is reconstructed.

Figure 2 shows a schematic diagram of a conventional single-photon counting instrument using a pulsed laser as an excitation source. An electrical pulse associated to the optical pulse is generated (e.g. by a photodiode or the electronics associated to the excitation source) and routed – through a constant-fraction discriminator – to the start input of the time-to-amplitude converter (TAC). Meanwhile, the sample is excited by the optical pulse and emits fluorescence. The optics is tuned (e.g., by means of a neutral density filter) so that the photomultiplier detects no more than one fluorescence photon for each exciting pulse. The corresponding electrical pulse is routed – through a constant-fraction discriminator – to the stop input of the TAC. The latter generates an output pulse whose amplitude is directly proportional to the delay time between the start and the stop pulses. The height analysis of this pulse is achieved by an analog-to-digital converter and a multichannel

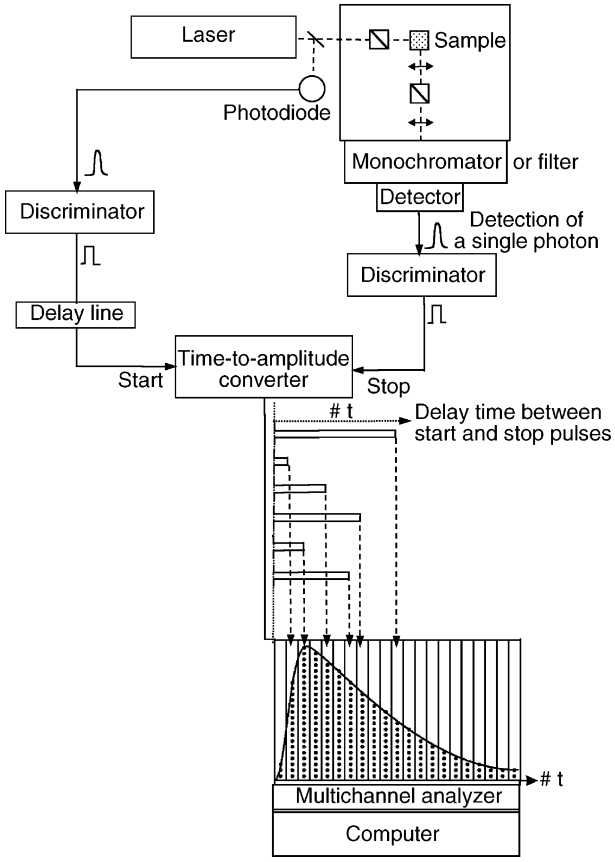

Figure 2 Schematic diagram of a single-photon timing fluorometer.

analyzer (MCA), which increases by one the contents of the memory channel corresponding to the digital value of the pulse. After a large number of excitation and detection events, the histogram of pulse heights represents the fluorescence decay curve.

Obviously, the larger the number of events, the better the accuracy of the decay curve. The required accuracy depends on the complexity of the δ-pulse response of the system; for instance, a high accuracy is, of course, necessary for recovering a distribution of decay times.

When deconvolution is required, the time profile of the exciting pulse is recorded under the same conditions by replacing the sample with a scattering solution (e.g., a suspension of colloidal silica (Ludox)).

It is important to note that the number of detected fluorescence photons must be kept much smaller than the number of exciting pulses ($<0.01-0.05$ stops per pulse), so that the probability of detecting two fluorescence photons per exciting photon is negligible. Otherwise, the TAC will take into account only the first fluorescence pulse and the counting statistics will be distorted: the decay will appear shorter than it is in reality. This effect is called the 'pile-up effect'.

Laser Sources for the Single-Photon Timing Technique

Mode-locked dye lasers and titanium-doped sapphire lasers are well suited to the single-photon timing technique: in fact, they can generate pulses over broad wavelength ranges, and the pulse widths are in the femtosecond and picosecond ranges with a high repetition rate. Flash lamps running in air, or filled with gas, can also be used, but the range of excitation wavelengths is limited; they deliver nanosecond pulses, and the repetition rate is not high (10^4-10^5 Hz). Dye lasers require the handling of large volumes of dye solutions which must be replaced when the dye is bleached. In contrast, the Ti:sapphire laser is a solid-state laser that does not have this drawback and delivers shorter light pulses. Moreover, long operational lifetime, operational simplicity, reliability, and broad tunability are distinct advantages. For these reasons, Ti:sapphire lasers have become more popular, and are described below.

Ti:sapphire lasers

Titanium-doped sapphire crystals are obtained by replacing a small fraction of the Al atoms of the host (Al_2O_3) with Ti atoms. When the concentration of Ti is low, the optical quality and the mechanical properties of Ti:sapphire crystals are comparable to those of ruby crystals in ruby lasers. The absorption spectrum of Ti:sapphire crystals exhibits a maximum at 490 nm and a shoulder at 540 nm. Therefore, pumping can be achieved by an Argon ion laser or a green solid-state laser. The emission spectrum ranges from 600 to 1,100 nm. Such a broad emission spectrum results from electronic coupling between the electronic levels of the 3d electrons with the lattice vibrations. Since excited-state absorption is not possible in the spectral region of the pump and the fluorescence spectrum, the tuning range is broad: it extends from 680 to 1,100 nm, i.e., almost over the entire fluorescence spectrum.

The width of the pulses that can be generated by Ti:sapphire lasers ranges from a few tens of femtoseconds to about 100 picoseconds. Commercially available Ti:sapphire lasers can operate either in the femtosecond configuration or in the picosecond configuration. In time-resolved fluorescence experiments using the single-photon timing technique, the instrument response is limited by the time response of the photomultiplier; the shortest width of this response that can be measured with the faster detectors (i.e., microchannel plate photomultipliers) is about 30–40 ps (see below). Therefore, there is no reason to operate the Ti:sapphire laser in the femtosecond configuration. In the picosecond configuration, the pulse width is $<2-100$ ps.

Figure 3 shows the six-mirror folded cavity design for the picosecond configuration in a Tsunami

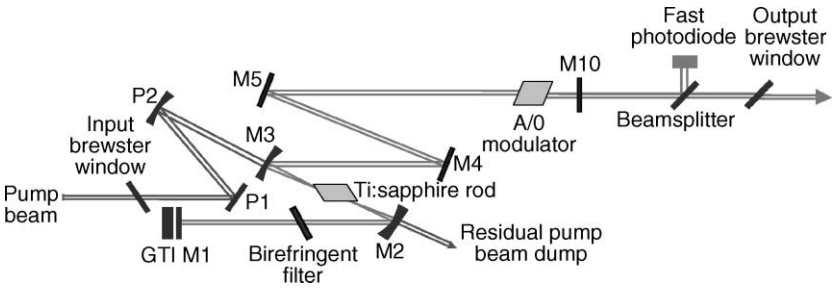

Figure 3 Beam path of the laser cavity of the Tsunami Ti:sapphire laser (Spectra Physics) operating in the picosecond configuration (Adapted from the Tsunami brochure with permission of Spectra Physics).

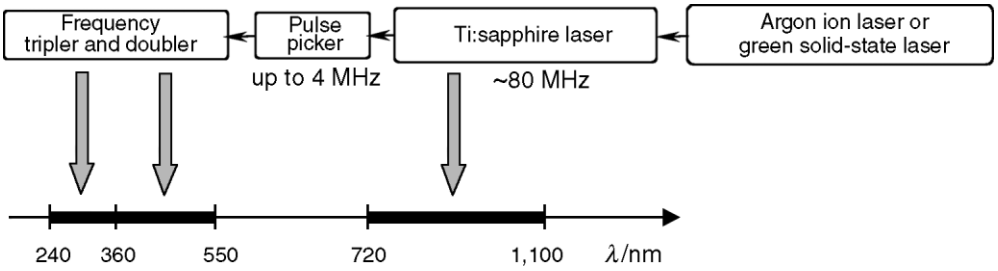

Figure 4 Schematics of the excitation system in time-resolved fluorescence experiments.

Ti:sapphire laser (Spectra Physics). A Brewster's angle acousto-optic modulator, driven by a low-power rf source, insures an 80 MHz repetition rate. Consequently, in contrast to standard passive mode-locking systems, the laser can operate for long periods without dropouts or shut-downs. Gires–Tournois Interferometer (GTI) mirror spacing is used for tuning the laser cavity. Wavelength tuning is achieved by means of a two-plate birefringent filter placed within the laser cavity at Brewster's angle. The tuning range depends on the mirror sets that are used. With broadband cavity mirrors, the entire tuning range of Ti:sapphire is covered, i.e., from below 700 nm to greater than 1,000 nm, and changes in wavelength can be made in a matter of minutes.

When pumping with a 10 W argon ion laser, the average output power is about 1.5 W at 800 nm and the pulse energy is about 15 nJ. Argon ion lasers can now be advantageously replaced by cw green solid-state lasers (532 nm) in which the gain medium ($Nd:YVO_4$) is pumped by diodes, and a LBO crystal placed inside the cavity ensures frequency doubling. These lasers offer several advantages: the head is compact and does not require external cooling water; it is insensitive to temperature, and thermal equilibration is very rapid.

Since the excited-state lifetime of fluorescent compounds can be as long as several hundreds of nanoseconds, the repetition rate of 80 MHz is too high to let the fluorescence of long lifetime samples vanish before a new exciting pulse is generated. Therefore, it must be limited to a few MHz, thanks to a pulse picker using a Bragg-angle acousto-optic modulator synchronized to the mode-locked 80 MHz pulse train. Selection of pulses from the train can thus be achieved at a maximum pulse selection rate of 8 MHz.

For excitation of fluorescent samples, wavelengths in the visible and UV regions are desirable. Frequency doublers and triplers using LBO and BBO crystals, respectively, have been designed with this aim. The possible tuning ranges are shown in Figure 4. When pumping with a 10 W argon ion laser, the average output powers are about 300 mW and 120 mW for frequency doubling and tripling, respectively.

With Ti-sapphire lasers and microchannel plate photomultipliers, decay times as short as 10 ps can be measured.

The results of an experiment are shown in Figure 5.

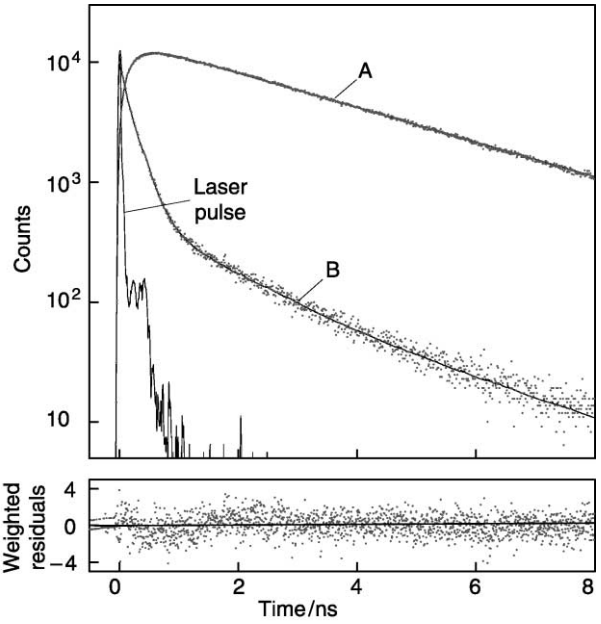

Figure 5 Example of data obtained by the single-photon timing technique using a Spectra-Physics setup composed of a titanium-sapphire Tsunami laser pumped by an argon ion laser, a pulse selector, and doubling (LBO) and tripling (BBO) crystals. The detector is a Hamamatsu MCP photomultiplier R3809U. The sample is a solution of DANS1 (a derivative of dansylamide) in a mixture CH_3CN/H_2O (60:40 v/v) at pH 0.8. Excitation wavelength: 286 nm. Channel width: 9.8 ps. A: Observation through a bandpass filter (300–370 nm) of the protonated form that undergoes photoinduced deprotonation. B: Observation through a cut-off filter ($\lambda > 400$ nm) of the neutral form; the observed risetime corresponds to the formation of the neutral form from the protonated form. Global analysis of the two curves leads to two time constants: 183 ± 9 ps and 3.01 ± 0.03 ns (Global $\chi^2_R = 1.26$) (Métivier R, Leray I and Valeur B, unpublished results. Métivier R, doctoral thesis, Ecole Normale Supérieure de Cachan, 2003).

Pulsed diode lasers

Picosecond diode laser heads offer an interesting alternative to mode-locked lasers and are much less expensive. They can produce light pulses as short as 50–90 ps with repetition rates from single shot to 40–80 MHz. Peak powers up to 500 mW can be obtained. However, the main disadvantage is the absence of tunability, and the number of wavelengths is limited: 375, 400, 440, 635 to 1,550 nm. No wavelength below 375 nm is presently available.

Phase-Modulation Fluorometers

In the frequency domain, the phase and modulation measurements can be taken by using either a cw laser and an optical modulator, or the harmonic content of a pulsed laser.

Phase Fluorometers Using a cw Laser and an Optical Modulator

The optical modulator is generally a Pockels cell. Low-power cw lasers are sufficient and not as expensive as pulsed lasers, so that one can afford several lasers of this type in order to get various excitation wavelengths. Available wavelengths from cw lasers are given in Table 1. A Xenon lamp can also be used; however, the optical modulator works better with a cw laser.

Figure 6 shows the schematic diagram of a multifrequency phase-modulation fluorometer using a cw laser and a Pockels cell. A beamsplitter reflects a few percent of the incident light towards a reference photomultiplier (via, or not, a cuvette containing a reference scattering solution). The fluorescent sample and a reference solution (containing either a scatter or a reference fluorescent compound) are placed in a rotating turret. The emitted fluorescence or scattered light is detected by a photomultiplier through a monochromator or an optical filter. The Pockels cell is driven by a frequency synthesizer and the photomultiplier response is modulated by varying the voltage at the second dynode by means of another frequency

Table 1 Examples of available wavelengths from low-power cw lasers

Laser	*Wavelength (nm)*
He–Cd	325; 442.5
He–Ne	543.3; 594; 611.9; 632.8
Ar^{+a}	457.9; 476.5; 488.0; 514.5

[a]High-power argon ion lasers can also provide wavelengths of 351.1 and 363.8 nm.

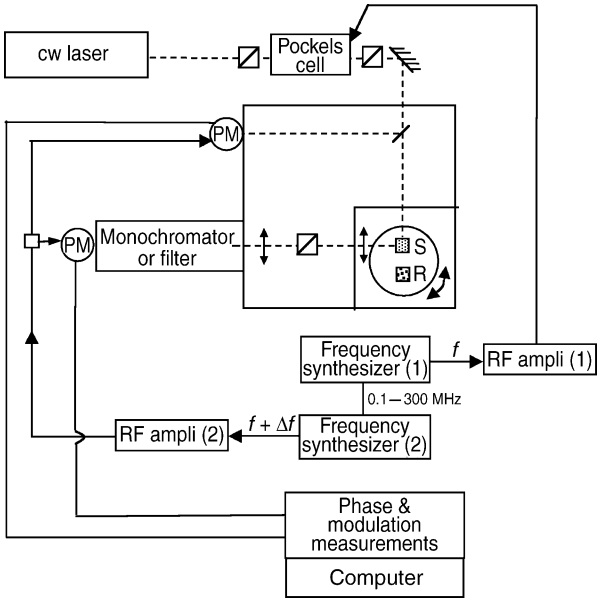

Figure 6 Schematic diagram of a multifrequency phase-modulation fluorometer using a cw laser and a Pockels cell (S: sample; R: reference; PM: photomultiplier).

synthesizer locked in phase with the first one. The two synthesizers provide modulated signals that differ in frequency by a few tens of Hz in order to achieve cross-correlation (heterodyne detection). This procedure offers excellent accuracy because the phase and modulation information contained in the signal is transposed to the low-frequency domain, where phase shifts and modulation depths can be measured with a much better accuracy than in the high-frequency domain.

Practically, the phase delay ϕ_R and the modulation ratio m_R of the light emitted by the scattering solution are measured with respect to the signal detected by the reference photomultiplier. Then, after rotation of the turret, the phase delay ϕ_F and the modulation ratio m_F for the sample fluorescence are measured with respect to the signal detected by the reference photomultiplier. The absolute phase shift and modulation ratio of the sample are then $\Phi = \phi_F - \phi_R$ and $M = m_F/m_R$, respectively.

Figure 7 shows an example of an experiment.

Phase Fluorometers Using the Harmonic Content of a Pulsed Laser

The type of laser source that can be used is exactly the same as that for single-photon timing pulse fluorometry (see above). Such a laser system that delivers pulses in the picosecond range, with a repetition rate of a few MHz, can be considered as an intrinsically modulated source. The harmonic content of the pulse train – which depends on the

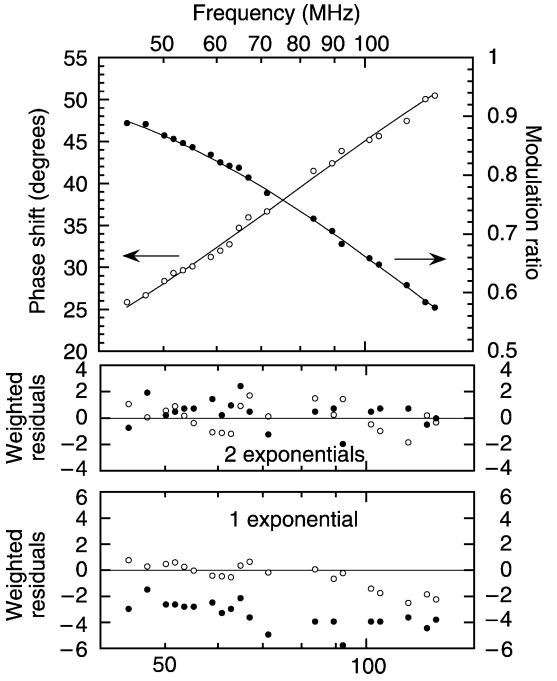

Figure 7 Example of data obtained by the phase and modulation technique using a fluorometer is equipped with a cw Omnichrome He–Cd laser (442 nm) and a Pockels cell operating at frequencies ranging from 0.1 to 200 MHz. The sample is a solution of a calcium complex of a crowned merocyanine (DCM-crown) in acetonitrile (observation through a Balzers bandpass filter centered at 581 nm). The solid line corresponds to the best fit with a biexponential decay. Weighted residuals are shown for the best fit with one and two exponentials. The time constants are 1.87 ± 0.04 and 0.35 ± 0.09 ns with fractional intensities of 0.85 and 0.15, respectively. The value of χ_r^2 is 1.01. (Redrawn from Martin MM, Plaza P, Meyer YH, *et al.* (1996) Steady-state and picosecond spectroscopy of Li^+ or Ca^{2+} complexes with a crowned merocyanine. Reversible photorelease of cations. *Journal of Physical Chemistry* 100: 6879–6888, with permission from the American Chemical Society).

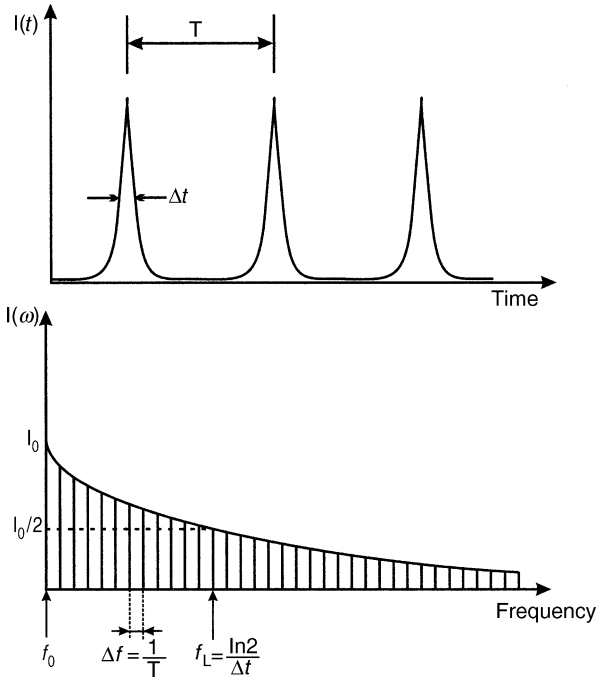

Figure 8 Harmonic content of a pulse train. Example of numerical values: $\Delta f = 4$ MHz; $\Delta t = 4$ Ps; $f_L = 44$ GHz.

pulse width (as illustrated in Figure 8) – extends to several gigahertz.

For high-frequency measurements, normal photomultipliers are too slow, and microchannel plate photomultipliers are required. However, internal cross-correlation is not possible with the latter and an external mixing circuit must be used.

The time resolution of a phase fluorometer, using the harmonic content of a pulsed laser and a microchannel plate photomultiplier, is comparable to that of a single-photon timing instrument using the same kind of laser and detector.

Data Analysis

In both pulse and phase fluorometries, the most widely used method of data analysis is based on a nonlinear least-squares method. The basic principle of this method is to minimize a quantity which expresses the mismatch between data and fitted function. This quantity is the reduced chi-square χ_r^2, defined as the weighted sum of the squares of the deviations of the experimental response $R(t_i)$ from the calculated responses $R_c(t_i)$:

$$\chi_r^2 = \frac{1}{\nu}\sum_{i=1}^{N}\left[\frac{R(t_i) - R_c(t_i)}{\sigma(i)}\right]^2 \qquad [20]$$

where N is the total number of data points and $\sigma(i)$ is the standard deviation of the ith data point, i.e., the uncertainty expected from statistical considerations (noise). ν is the number of degrees of freedom ($\nu = N - p$, where p is the number of fitted parameters). The value of χ_r^2 should be close to 1 for a good fit.

In the single-photon timing technique, the statistics obey the Poisson distribution and the expected deviation $\sigma(i)$ is approximated to $[R(t_i)]^{1/2}$ so that eqn [20] becomes

$$\chi_r^2 = \frac{1}{\nu}\sum_{i=1}^{N}\frac{[R(t_i) - R_c(t_i)]^2}{R(t_i)} \qquad [21]$$

In phase fluorometry, no deconvolution is required: curve fitting is performed in the frequency domain, directly using the variations of the phase shift Φ and the modulation ratio M as functions of the modulation frequency. Phase data and

modulation data can be analyzed separately, or simultaneously. In the latter case the reduced chi-squared is given by

$$\chi_r^2 = \frac{1}{\nu}\left[\sum_{i=1}^{N}\left[\frac{\Phi(\omega_i) - \Phi_c(\omega_i)}{\sigma_\Phi(\omega_i)}\right]^2 + \sum_{i=1}^{N}\left[\frac{M(\omega_i) - M_c(\omega_i)}{\sigma_M(\omega_i)}\right]^2\right] \quad [22]$$

where N is the total number of frequencies. In this case, the number of data points is twice the number of frequencies, so that the number of degrees of freedom is $\nu = 2N - p$.

In addition to the value of χ_r^2, it is useful to display graphical tests. The most important of them is the plot of the weighted residuals defined as

$$W(t_i) = \frac{R(t_i) - R_c(t_i)}{\sigma(i)} \quad [23]$$

where $\sigma(i) = [R(t_i)]^{1/2}$ for single-photon counting data. The fit is satisfactory when the weighted residuals are randomly distributed around zero.

Concluding Remarks

From the instrumental point of view, the latest generations of pulse and phase fluorometers both use pulsed lasers (usually Ti:sapphire lasers) and microchannel plate detectors; only the electronics is different. Since the instrument response is mainly limited by the time response of the detector, the time resolution is the same for both techniques. Moreover, the optical module is identical so that the total cost of instrumentation is similar.

There are, however, significant differences between pulse and phase fluorometers from the methodological point of view. In pulse fluorometry, the single-photon timing technique offers various advantages: direct visualization of the fluorescence decay; high sensitivity; outstanding dynamic range and linearity; and well-defined statistics (Poisson distribution) allowing the accurate weighing of each point in data analysis. In phase-modulation fluorometry, the main advantage is that no deconvolution is necessary, while this operation is often necessary in pulse fluorometry and requires great care in recording the instrument response, especially for very short decay times. Moreover, the short acquisition time for phase shift and modulation ratio measurements at a given frequency is a distinct advantage.

Introduction

In this article we explore the use of ultrashort pulsed lasers in time-resolved fluorescence measurements for the study of the dynamics of excimer formation and energy transfer/migration in synthetic aromatic polymers. The temporal profile of monomer and excimer emission, and the use of time-resolved fluorescence polarization approaches are discussed.

The use of lasers in chemistry has most often exploited the high degree of spectral purity achievable with these devices, in both photochemical and

high-resolution spectroscopic applications. Through the use of lasers, we also have the ability to generate pulses of light of ultrashort duration (a few femtoseconds) and of incredibly high peak powers (petawatts), characteristics significantly beyond those achievable with conventional (incoherent) light sources. This enables the kinetics of the many photophysical and photochemical processes that occur on ultrafast time-scales with high efficiency within polymers, to be determined through various time-resolved measurements.

These processes are dealt with in detail in specialist photochemistry textbooks and so knowledge of the terms associated with photochemistry and photophysics is assumed (e.g., electronic configurations, orbitals, spin, multiplicity, etc.).

Following the absorption of light, an isolated chromophore will be in one of its excited electronic and vibrational states. Once formed, the excited state of a molecule will only survive for a limited time, with the molecule losing its excess energy to return to a preferred lower energy state (electronic configuration). It can do this through a number of spontaneous, radiative, and nonradiative deactivation processes, each with its own characteristic rate constant k_{ij}. Nonradiative pathways include internal conversion (IC), such as intramolecular vibrational redistribution, and vibrational coupling to the bath, and inter-system crossing (ISC) between singlet and triplet manifolds. Radiative pathways involve the emission of a photon of light, in the form of fluorescence or phosphorescence.

The time the molecule spends in the excited state is determined by the rates of all the pathways that contribute to the overall deactivation of that state. The lifetime, τ, of a singlet state is therefore defined as:

$$\tau = \frac{1}{k_{\mathrm{ISC}} + k_{\mathrm{IC}} + k_{\mathrm{Rad}} + \cdots} = \frac{1}{\sum k_{ij}} \qquad [1]$$

In systems of higher chromophore concentration, such as aromatic-containing polymers, additional, bimolecular pathways are available through which the excess excited state energy may be dissipated, making it rare that a single fluorescence 'lifetime' is observed from polymer systems. The observation of complex (multi- or nonexponential) fluorescence decay profiles sometimes invokes the use of the terms 'average lifetimes' or 'lifetime distributions'.

The complex nonexponential fluorescence decay behavior observed, particularly from polymer systems, has been variously attributed to one or more of the following factors: molecular aggregation (e.g., excimer/exciplex equilibria); acid–base equilibria (e.g., proton transfer); one-, two-, or three-dimensional energy transfer and energy migration (and variations in the singlet energy migration length); electron transfer; molecular motion (translational diffusion, rotational relaxation); vibrational or solvent relaxation; concentration quenching; fluorescent impurities, etc. The kinetics of excimer formation are further complicated by heterogeneity of kinetically distinct monomer and/or excimer species, configurational and conformational influences upon excimer formation, and the time dependence of energy trapping (excimer formation) through nonequilibrium diffusion-controlled processes. Here, we will concentrate on excimer formation and energy migration in synthetic aromatic polymers, as shown schematically in Figure 1.

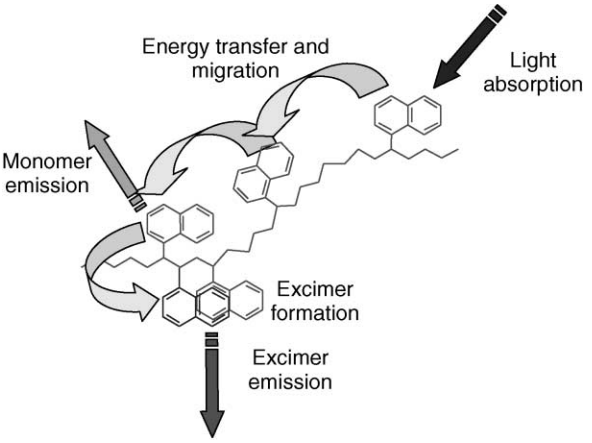

Figure 1 Schematic representation of some of the photophysical processes in polymers.

Ultrafast Laser Spectroscopic Techniques

A wide range of experimental techniques and instrumentation is available for the study of time-resolved processes in polymers. The most widely used methods rely on the detection of emission from the polymer. Fluorescence-based techniques are popular for investigating time-dependent processes in polymers, since the time-scales involved in many of the photochemical and photophysical processes discussed correspond with the time-scales on which fluorescence occurs (normally on the subpicosecond to nanosecond time-scales). Phosphorescence usually occurs on significantly longer time-scales and therefore is less likely to be competitive with fluorescence or other radiative or nonradiative deactivation pathways under normal conditions. Fluorescence-based techniques are attractive for reporting on a number of time-dependent processes since fluorescence is inherently multidimensional, it can be readily resolved temporally, and fluorescence detection can

be extremely sensitive, achieving single photon and single molecule detection levels.

Amongst the most commonly used fluorescence-based techniques are: time-correlated single photon counting (TCSPC, or single photon timing), fluorescence transient digitization, and ultrafast streak cameras. Methods such as transient absorption (flash photolysis) can also provide some details regarding the identity of short-lived species formed following photo-excitation. Other ultrafast laser techniques have been applied to the study of time-dependent processes in polymers in order to achieve higher temporal resolution. So-called pump–probe methods provide the ultimate in time-resolution and can be combined with fluorescence detection through the use of Kerr shutters or ultrafast fluorescence upconversion techniques. Other, more complex pump–probe methods, such as transient grating and multiple pulse photon echo measurements, are potentially very powerful tools in the study of time-resolved processes in polymers.

The generation of short pulses of light can be achieved through numerous mechanisms, including active or passive mode-locking and Q-switching techniques, and superradiance processes (e.g., in nitrogen lasers). Lasers capable of producing short (~ns) pulses of light by Q-switching are usually characterized by high energies per pulse (from μJ up to many hundreds of mJ/pulse) at low (~Hz–kHz) pulse repetition rates. Lasers producing pulses of ultrashort duration (often in the picosecond or femtosecond region) through mode-locking techniques, characteristically operate at high pulse repetition rates (~MHz) and with lower energies per pulse (~nJ/pulse). It should be noted that even pulses of a few nJ energy delivered in ~100 fs, still have peak powers of tens of kW. These high peak powers enable the generation of a range of excitation wavelengths suitable for the study of polymer systems through nonlinear optical wavelength conversion processes, such as second-harmonic generation (SHG) and optical parametric oscillation (OPO) devices.

Excimer Formation

Excimers (or *excited-state dimers*) are formed when an aromatic molecule, while in its excited electronic state, $^1M^*$, interacts with a second molecule of the same chemical type in its ground electronic state, ^1M. Excimer formation is often observed in concentrated molecular systems such as concentrated solutions and molecular crystals; however, it can also occur in dilute solutions of polymers containing aromatic chromophores, or in the confined environment of solid polymer systems such as homopolymer films.

The structure of excimers in solution is generally thought to be a face-to-face, coplanar, sandwiched, or in some cases, partially eclipsed arrangement of the two constituent aromatic moieties, which attempt to adopt the lowest possible energy configuration, with a separation of 3–4 Å, as depicted in Figure 2. A range of possible excimer configurations may exist rather than just the two extremes.

A feature of excimers is that they have a dissociative ground state (Figure 3), i.e., they do not exist prior to the absorption of light by one monomer chromophore and thus cannot be formed directly without the coming together of the two constituent chromophores within the lifetime of the $^1M^*$. Excimers, being of lower energy than the corresponding excited monomer species and with this dissociative ground state, usually exhibit characteristically

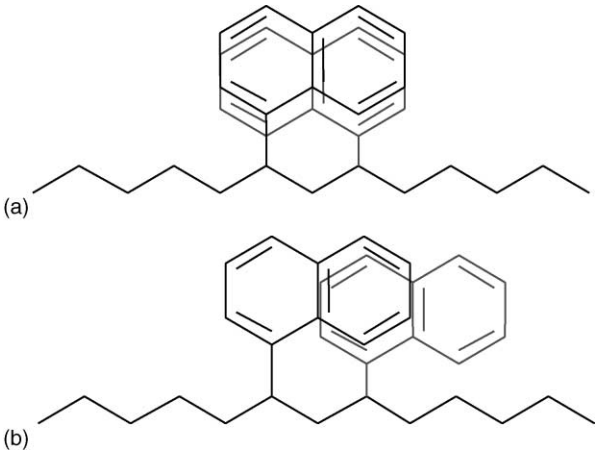

Figure 2 (a) Sandwiched and (b) partially eclipsed excimer configurations.

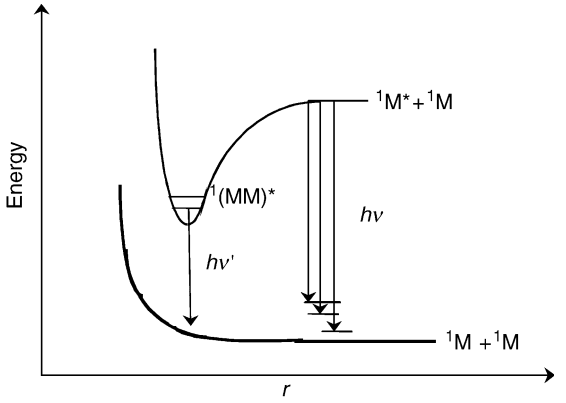

Figure 3 Schematic potential energy diagram for excimer formation and decay. r represents the monomer–monomer separation.

broad, structureless emission to the red of the monomer emission (Figure 4). Upon the emission of fluorescence from an excimer, the complex loses its excess energy and dissociates back to two ground state monomer units (i.e., 2 ^{1}M). Excimers may also dissociate back to a noninteracting pair of $^1M^*$ and ^{1}M.

Excimer formation of simple aromatic molecules in solution is often modeled on the kinetic scheme proposed by Birks and co-workers (Figure 5). From Figure 5, if a δ-pulse excitation, represented by $h\nu_{abs}$, is used to produce an initial concentration of excited singlet monomer molecules, $[^1M^*]_o$, then such a scheme results in the following rate equations:

$$\frac{d[^1M^*]}{dt} = k_{MD}[^1(MM)^*] - X[^1M^*] \quad [2]$$

$$\frac{d[^1(MM)^*]}{dt} = k_{DM}[^1M][^1M^*] - Y[^1(MM)^*] \quad [3]$$

where $X = k_{FM} + k_{NM} + k_{DM}[^1M^*] = k_M + k_{DM}[^1M]$, $Y = k_{FD} + k_{ND} + k_{MD} = k_D + k_{MD}$.

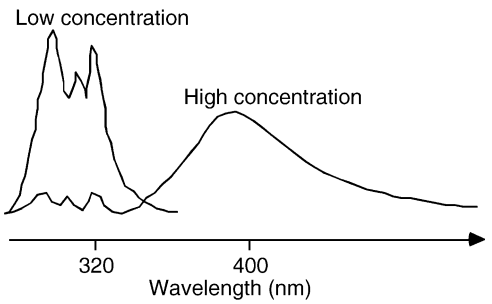

Figure 4 Schematic representation of monomer and excimer emission.

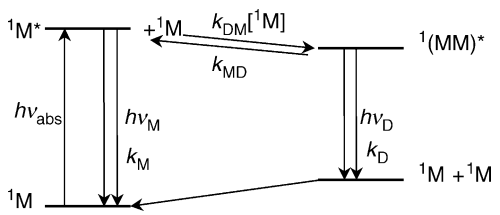

Figure 5 Kinetic scheme for excimer formation where $h\nu_M$ and $h\nu_D$ represent the emission of photons by the monomer and excimer species respectively, k_M and k_D comprise the sum of the various rate constants for all deactivation pathways for the monomer and excimer respectively (excluding k_{MD} and k_{DM}) (e.g., $k_M = k_{FM} + k_{NM}$ where k_{FM} and k_{NM} are the radiative (fluorescence) and nonradiative deactivation rate constants respectively of the monomer).

Solving these rate equations and applying the initial conditions $[^1M^*]_t = [^1M^*]_o$ and $[^1(MM)^*]_o = 0$ at $t = 0$, yields expressions given below for the decay of monomer and excimer fluorescence intensity with time. The emission intensity (monitored in a spectral region in which only the monomer $[^1M^*]$ species emits), will have the temporal form given by eqn [4]:

$$i_M(t) = k_{FM}\frac{[^1M^*]}{[^1M^*]_o} = \left[k_{FM}\frac{(\lambda_2 - X)}{(\lambda_2 - \lambda_1)}\right]\left[\exp(-\lambda_1 t) + A\exp(-\lambda_2 t)\right] \quad [4]$$

where

$$A = \frac{(X - \lambda_1)}{(\lambda_2 - X)},$$

$$\lambda_{1,2} = \frac{1}{2}\left[X + Y \mp \left\{(Y - X)^2 + 4k_{MD}k_{DM}[^1M^*]\right\}^{1/2}\right]$$

The emission intensity collected from a spectral region in which the excimer ($^1[MM]^*$) species only emits, will have the temporal form given by eqn [5]:

$$i_D(t) = k_{FD}k_{DM}\frac{[^1D^*]}{[^1M^*]_o} = \left[\frac{k_{FD}k_{DM}[^1M]}{(\lambda_2 - \lambda_1)}\right]\left[\exp(-\lambda_1 t) - \exp(-\lambda_2 t)\right] \quad [5]$$

If excimer formation follows Birks' scheme, then the decay profile of the monomer fluorescence should therefore be described by the sum of two exponential decay terms, and the excimer emission by an exponential growth term and a decay term (Figure 6). Only two decay constants, λ_1 and λ_2, should be required to fit both the monomer and excimer fluorescence profiles successfully. This is often not observed, which has led to the introduction of more complex interpretations.

In synthetic aromatic polymers, the effective local concentration of the aromatic molecules can be high while the concentration of polymer chains in solution may be very low. This means that excimer formation can be significant in such polymers, even in dilute solution. In fact, in some polymers the emission is dominated by excimers over monomers. The fact that the excimers are of lower energy than the corresponding excited monomer species also means that they can act as effective traps of excitation energy that might be migrating/relocating within a polymer chain as discussed below.

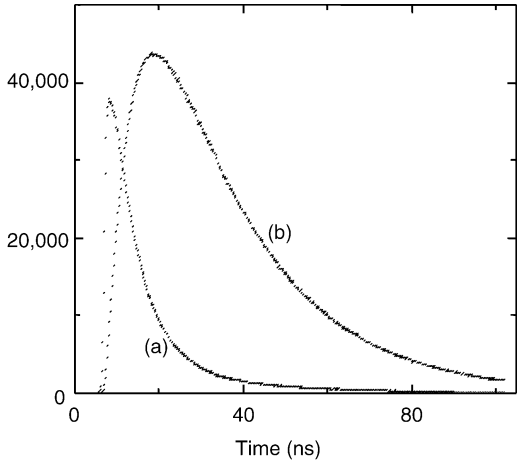

Figure 6 Examples of (a) monomer and (b) excimer fluorescence decays.

Excimer formation in solutions of aromatic polymers is generally thought to proceed via a complicated route that may involve a combination of electronic energy transfer and migration, segmental rotation, and chromophore diffusion. It is believed that energy migrates along a polymer chain until sites suitable for excimer formation are encountered, at which point the energy is trapped. A number of mechanisms for the formation of suitable excimer sites in polymers are then conceivable. These include:

(i) interactions between chromophores belonging to different chains (this *inter*molecular excimer formation is highly concentration dependent);
(ii) interactions between two chromophores far removed from each other, but on the same chain. This necessitates mainchain conformational changes and side group motions during the excited state lifetime, so as to bring both molecules together;
(iii) near neighbor interactions (c.f. Hirayama's '$n = 3$' rule). The configuration required for excimer formation need not exist prior to excitation provided that the two constituent groups can attain the required geometry within the lifetime of the excited chromophore; or
(iv) preformed sites, suitable for excimer formation, present in the polymer before the initial absorption of light occurs. These may be formed by interactions between nearest neighbor chromophores or between two chromophores on loops of the same, or different chains in cases where chain motion is restricted.

The first two of these mechanisms depend upon segmental motion of the polymer chain and the third mechanism may depend upon rotation of the chromophore/s to adopt the close proximity and optimum orientational configuration required for excimer formation. In solution, this may be, at least partially, diffusion-controlled, causing a dominant complicating factor in the kinetics of excimer formation in polymeric systems. One approach is therefore to substitute a time-dependent expression for the rate coefficient of excimer formation, $k_{DM}(t) = A + B/\sqrt{t}$, (based on the Einstein–Smoluchowski diffusion theory), for k_{DM}, into the rate equations. Such an approach produces the following expression for the time dependence of the monomer fluorescence, $I_M(t)$ in the presence of diffusion-controlled excimer formation and the absence of excimer back dissociation:

$$I_M(t) = A \exp\left\{ - at - b\sqrt{t}\right\} \qquad [6]$$

In some cases, such as when excimer back dissociation cannot be neglected, more complex functional forms have been derived, such as:

$$I_M(t) = A \exp\left\{ - at - b\sqrt{t}\right\} + B \exp\left\{ - t/\tau\right\} \qquad [7]$$

Similar expressions can be derived for the time dependence of the excimer fluorescence, $I_E(t)$. More detailed expressions for the term $k(t)_{DM}$, involving the complete form of the diffusion rate coefficient, have also been used in such approaches.

A related approach is the concept of 'convolution kinetics', in which the intimate dependence of excimer formation upon the monomer decay is emphasized. Once formed, the excimer is assumed to decay exponentially. The excimer fluorescence temporal profile is predicted to take the form:

$$I_E(t) = k_1(t) I_M(t) \otimes \exp\left(\frac{-t}{\tau}\right) \qquad [8]$$

where $\otimes$ represents the convolution integral and $I_E(t)$ and $I_M(t)$ are the measured decay profiles in the excimer and monomer emission regions respectively.

Electronic Energy Transfer, Energy Migration and Trapping

In polymers the high local concentration of chromophores makes additional deactivation pathways competitive with the other photophysical processes.The excess energy may transfer from the excited fluorophore of interest to a lower energy chromophore. Three of the more common possible mechanisms, through which energy transfer can occur, are:

(i) *Radiative* ('*trivial*') – involves the reabsorption of donor emission by an acceptor chromophore.

(ii) *Resonance* (*Dipole–Dipole*, *Förster*) – long-range (15–100 Å), nonradiative, single-step energy transfer process arising from Coulombic (dipole–dipole) interactions between an excited-state donor chromophore, D^*, and an initially unexcited acceptor, *A*. Förster derived a statistical expression for the (first-order) rate constant, for such a process, considering three-dimensional, dipole–dipole interactions between stationary molecules:

$$k(R)_{D^*\to A} = \frac{9000\kappa^2\phi_o \ln 10}{128\pi^5\eta^4 N\tau_D R^6}\int_0^\infty \frac{f_D(\bar{\nu})\varepsilon_A(\bar{\nu})}{\bar{\nu}}d\bar{\nu} = \frac{1}{\tau_D}\left(\frac{R_o}{r_D}\right)^6 \quad [9]$$

where R is the donor–acceptor distance, ϕ_o is the quantum yield for emission from the donor in the absence of acceptor molecules, η is the refractive index of the solvent, τ_D is the lifetime of the donor excited state (reduced by the onset of electronic energy transfer), N is Avogadro's number, κ is a constant dependent on the mutual orientation of the donor and acceptor molecules, and the integral term is a measure of the spectral overlap between the donor emission profile, $f_D(\bar{\nu})$ (in quanta cm^{-1} and normalized to unit area) and the acceptor absorption profile, $\varepsilon_A(\bar{\nu})$ (converted to molar extinction coefficients and measured on a wavenumber scale). R_o is the critical transfer distance, at which the probability of resonance transfer, $k(R)_{D^*\to A}$, is equal to the probability of spontaneous decay, $1/\tau_D$.

(iii) *Exchange mechanism* – also a nonradiative, single-step process but involves the exchange of electronic excitation when the donor and acceptor are close enough so that their electron clouds overlap. Consequently it only operates over small distances. Dexter has derived a rate expression for exchange energy transfer, again assuming that the donor and acceptor molecules are stationary:

$$k_{D^*\to A} = \left(\frac{2\pi}{\hbar}\right)Z^2\int f_{D^*}(\bar{\nu})\varepsilon_A(\bar{\nu})d\bar{\nu} \quad [10]$$

where $Z^2 = K^2\exp(-2R/L)$ and K and L are simply constants.

It has been clearly demonstrated that energy transfer, from pendant aromatic monomer units to chemically bound acceptor chromophores, can occur with high efficiency and is influenced significantly by polymer structure and conformation.

In addition to energy transfer between D^* and A (being different chemical species), more than one exchange of excitation energy between chemically and spectroscopically identical chromophores, attached by covalent bonds to a polymer chain, can occur. A single step between identical units is still termed energy transfer, while more than one such step in a sequence would constitute intramolecular energy migration.

Energy migration is a long-range process, thought to occur via a series of energy transfer steps occurring between chromophores, either: (i) along the polymer chain (often the adjacent groups); (ii) across loops in a single polymer chain; or (iii) across different polymer chains. The migration continues until either a trap site is encountered or one of the chromophores excited in the migration process deactivates spontaneously. Each step is believed to occur with a probability defined by the exchange or Förster mechanisms, but since the energy transfer occurs between donor and acceptor groups, which are of the same type, the spectral overlap integral involved in both mechanisms will usually be small. The distances over which such energy transfer can occur therefore cannot be large and typically takes values of $<$10–20 Å. It is worth noting that many authors consider the energy to migrate as an incoherent exciton (where the term exciton is used in a much looser sense than is customary among solid-state physicists).

Long-range energy migration can only occur by energy transfer from the initially excited chromophore to ground state chromophores of the same, or lower, energy. If energy transfer is favorable between one chromophore and another of the same energy, then back transfer to the initially excited chromophore is also highly probable. When there is a change in the emission and absorption dipole orientations, caused by rotation of the chromophores relative to one another on the time-scale of the energy transfer step, or the transfer is to a chromophore of significantly lower energy, then the probability of energy transfer back to the original chromophore might be reduced. The lower energy chromophores on the polymer chain may therefore act as 'traps' of the excitation originally absorbed by a higher energy chromophore, even in the absence of excimer energy trap sites.

Various approaches have been proposed for modeling the kinetics of energy migration. One can consider the time-dependent nature of each energy transfer step of the migration process, and introduce a time-dependent rate coefficient for each step of the energy migration process, $k_{DD}(t)$. The form for $k_{DD}(t)$ by Sienicki *et al.*, is given by eqn [11], which leads to nonexponential functions predicted for the ensemble averaged probability that an originally excited donor

molecule is still excited at time t:

$$k_{DD}(t) = \left(\frac{\Delta}{n}\right)\gamma_\Delta c_D \Gamma(1-\Delta/n)\left(\frac{t}{\tau_{OD}}\right)^{\Delta/n-1} \quad [11]$$

where $\Delta(=1, 2, 3)$ is the dimensionality of the medium, $n(=6, 8, 10,\ldots)$ is the order of the interaction, τ_{OD} is the lifetime of the donor fluorescence, $\Gamma(x)$ is the gamma function, γ_Δ is a constant dependent upon Δ and c_D is the donor concentration.

Energy migration has also been considered as a diffusion-like process, and the Smoluchowski diffusion theory adopted. The rate coefficient for energy migration, $k(t)_{EM}$, is then expressed in a form similar to the time-dependent rate coefficient for partially diffusion-controlled reactions (eqn [12]). In this type of treatment, the rate of change of the concentration of excited monomer chromophores, $^1M^*$, is assumed to be given by eqn [13]:

$$k(t)_{EM} = 4\pi N'_A R D \rho\left[1 + R\rho(\pi D t)^{-1/2}\right] \quad [12]$$

$$\frac{d[^1M^*]}{dt} = I_o - \left(\frac{1}{\tau_o} + k(t)_{EM}\right)[^1M^*] \quad [13]$$

In these expressions, τ_o is the reciprocal of the sum of the rate constants for radiative and nonradiative deactivation, ρ is the reaction probability per collision, R is the interaction distance, and N'_A is the number density of the energy acceptors or traps ($N'_A = NC_A$, with the concentration of acceptors, C_A, in mol cm^{-3}). D is the mutual diffusion coefficient which can be replaced by a migration coefficient, Λ, R can be replaced by the Förster critical transfer distance, R_o, and the reaction probability, ρ, can be set to 0.5 (since R_o is the distance at which the probability of energy transfer is 0.5). This leads to a simplified expression for $k(t)_{EM}$, which can be substituted into eqn [13], to produce an expression (eqn [14]) for the monomer decay:

$$I(t) = A\exp\left(-\left(\frac{1}{\tau_o} + 2\pi N'_A R_o \Lambda[^1M^*]\right)t - 2N'_A R_o^2(\pi\Lambda)^{1/2}[^1M^*]\sqrt{t}\right) \quad [14]$$

Yokota and Tanimoto have also developed a statistical representation of Förster's theory and derived an expression for dipole–dipole transfer in a fluid medium in which the distribution of excited-state donor and acceptor molecules is determined, both by diffusion and by the decay and transfer of the donor excited state. According to the Yokota and Tanimoto approach, the decay law is approximated by the expression:

$$I(t) = A\exp\left\{\frac{-t}{\tau_o} - 2B\delta\left(\frac{-t}{\tau_o}\right)^{1/2}\right\} \quad [15]$$

where $\delta = [C]/[C]_o$ (C_o is the critical molar concentration of acceptor molecules given by: $[C_o] = 3000/2\pi^{3/2}NR_o^3$, and B is a complex, time-dependent function given by: $B = (1 + 10.87x + 15.5x^2 / 1 + 8.743x)^{3/4}$ with $x = D\alpha^{-1/3}t^{2/3}$, $\alpha = R_o^6/\tau_o$ and D is the 'diffusion coefficient' representing energy migration.

Emission depolarization is often exploited in the study of energy migration in polymers. Only molecules with some vector component of their absorption transition dipole lying parallel to the plane of polarization of the incident radiation, will absorb incoming radiation. In the absence of angular motion of the absorbing chromophore within the lifetime of the excited state, emission from the same chromophore will also be highly polarized; however, upon each step in the energy migration process, some loss of polarization will be incurred (**Figure 7**). The extent of depolarization of emission is usually referred to by the term fluorescence anisotropy, $r(t)$ (eqn [16]):

$$r(t) = \frac{I_\parallel(t) - I_\perp(t)}{I_\parallel(t) + 2I_\perp(t)} \quad [16]$$

The rate of energy migration can be estimated directly through observation of the time-dependent decay of $r(t)$ in the absence of other fluorescence depolarizing processes, such as molecule rotation (**Figure 8**).

One of the important properties which characterizes excitation energy transport in a system of n identical molecules, which are distributed randomly in space, is the Green function, $G(r,t)$. The Green function can be thought of as the time-dependent probability of finding an excitation at position r on the polymer chain at time t. It has been shown that the overwhelming contribution to fluorescence polarization is due to fluorescence from the sites that were initially excited. Thus, $G^s(r,t)$ is directly related to the fluorescence anisotropy if the polarization memory of secondary excited molecules can be neglected. The $r(t)$ for donor–donor energy transfer is then given by:

$$r(t) = \alpha r_{rot}(t) G^s(t) \quad [17]$$

in which r_{rot} describes the anisotropy in the absence of energy transfer, i.e., in the presence of chromophore

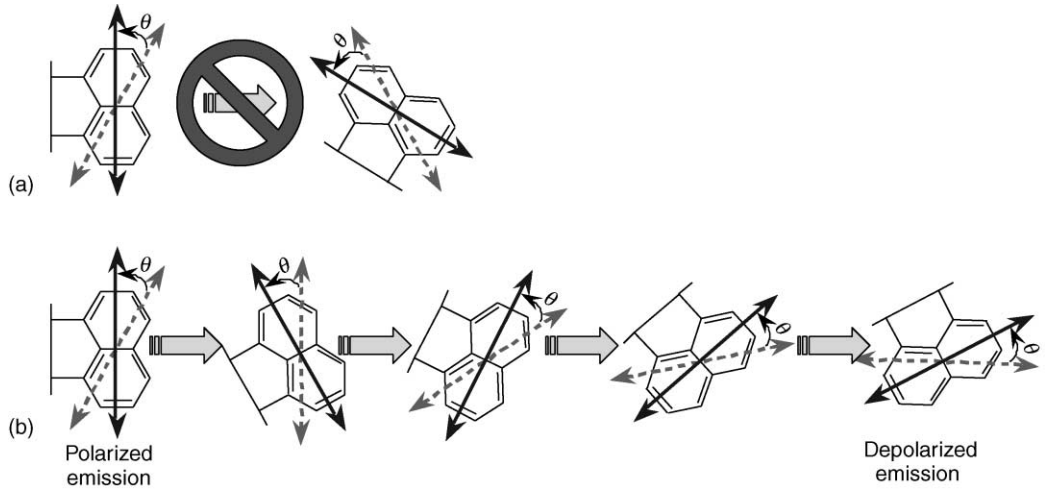

Figure 7 Schematic representation of energy migration. θ is the inherent angle between the donor emission (dotted arrow) and acceptor absorption (solid arrow) transition dipoles of the chromophore (a) orthogonal donor emission and acceptor absorption dipoles – no energy transfer/migration, emission depolarized only due to θ. (b) some vector component of the absorption dipole of the acceptor is parallel with that of the donor emission dipole – this and subsequent energy transfer steps can occur resulting in loss of emission polarization.

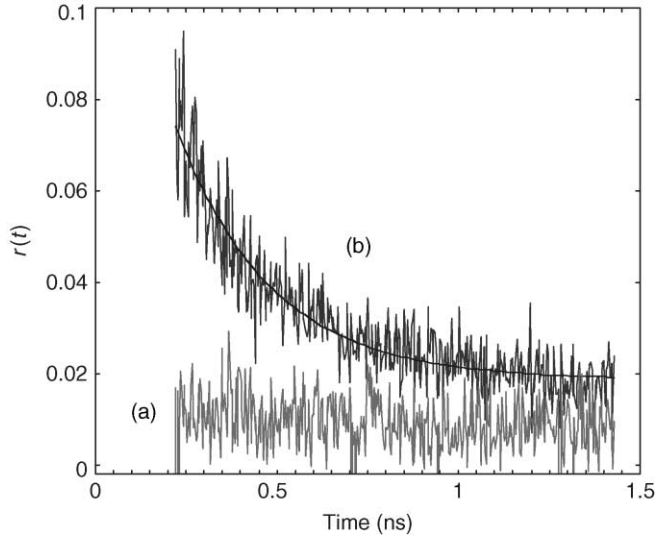

Figure 8 Temporal decays of $r(t)$ from (a) a polymer in which emission depolarization due to energy migration is complete on ultrafast time-scales, and (b) a polymer in which the rate of energy migration has been inhibited. Emission collected from polymers in frozen glass to exclude polymer motion contributions to emission depolarization.

rotation only, and α is the anisotropy from time-independent sources of depolarization.

The determination of the functional form of $G^s(r,t)$, resulting from excitation energy migration in polymer systems, is a challenging theoretical problem to which a number of approaches have been applied. The Gochanour, Anderson and Fayer approach has had some success in arriving at an expression for $G^s(r,t)$, represented as the time decay of emission polarization curves.

Polymeric systems that undergo energy migration, yet contain no excimer forming or other nonmonomeric, energy-trapping sites, are rare. In the presence of singlet energy traps, the problem can be treated as being analogous to energy transfer (via the Förster mechanism), following a diffusive process in a similar manner to that described above.

Fredrickson and Frank have derived expressions for the temporal decays of the monomer and excimer fluorescence when one-dimensional electronic singlet

energy migration is the major excimer-forming path, and segmental rotation and chromophore diffusion are considered. The Fredrickson and Frank model assumes inherently that excimers are formed predominantly via a nearest-neighbor mechanism, where rapid energy migration is at least an order of magnitude faster than any competing rotationally sampled pathways. The expressions for the fluorescence decay of both the monomer, $I_M(t)$, and excimer species, $I_E(t)$, are highly nonexponential, with the expression for $I_M(t)$ being given by eqn [18]:

$$I_M(t) = Q_{fm} k_m (1-q)^2 \times \exp[(4q^2 W - k_m - k_{rot})t]\mathrm{erfc}[2q(Wt)^{1/2}] \quad [18]$$

In eqn [18], Q_{fm} is the quantum efficiency for monomer fluorescence and k_m is a rate constant, which encompasses the total rate of monomer decay by radiative and nonradiative pathways in the absence of energy migration and rotational sampling. Similarly, k_{rot} represents the rate at which an excited monomer is transformed into an excimer by segmental rotation. The parameter W represents the rate constant for nearest-neighbor electronic energy transport between the donor (monomer) chromophores, averaged over both the transition moment orientation and the interchromophore separation associated with each dyad.

Energy transfer from pendant aromatic monomer units to a specific chemically bound acceptor chromophore can occur in some polymers following energy migration. This phenomenon is known as the 'antenna effect', which has commercial applications such as in the sensitization of photo-oxidation–reduction, i.e. reactions, in the stabilization of polymers against photodegradation or in the modeling of photosynthesis by light harvesting. The kinetic behavior of such processes is yet to be modeled definitively, but the approaches discussed above (and others) have been used with varying degrees of success to date.

List of Units and Nomenclature

Ångstrom (Å)	10^{-10} m
chromophore	An aromatic molecule that absorbs (and may emit) light
exciton	An excited state localized on a particular chromophore at any given time
femtoseconds	10^{-15} s
intermolecular	Occurring between molecules or polymer chains
intramolecular	Occurring within a single molecule or polymer chain
petawatts	10^{15} W
δ-pulse excitation	Excitation by an infinitely short laser pulse

Introduction

Optical coherence tomography (OCT) is an emerging imaging technique for a wide range of biological, medical, and material investigations. OCT was initially developed for imaging biological tissue because it permits the imaging of tissue microstructure *in situ*, yielding micron-scale image resolution without the need for excision of a specimen and tissue processing. OCT is analogous to ultrasound B-mode imaging except that it uses low-coherence light rather than sound and performs cross-sectional imaging by measuring the backscattered intensity of light from structures in tissue. The OCT image is a gray-scale or false-color two-dimensional representation of backscattered light intensity in a cross-sectional plane. The OCT image represents the differential backscattering contrast between different tissue types on a micron scale. Because OCT performs imaging using light, it has a one to two order-of-magnitude higher spatial resolution than ultrasound and does not require contact with the specimen or sample.

OCT was originally developed and demonstrated in ophthalmology for high-resolution tomographic imaging of the retina and anterior eye. Because the eye is transparent and is optically accessible, it is well suited for diagnostic OCT imaging. OCT is promising for the diagnosis of retinal disease because it can provide images of retinal pathology with 10 micron resolution, almost one order-of-magnitude higher than previously possible using ultrasound. Recently, OCT has been applied for imaging in a wide range of nontransparent tissues. In tissues other than the eye, the imaging depth is limited by optical attenuation due to scattering and absorption. Ophthalmic imaging is typically performed at 800 nm wavelengths. However, because optical scattering decreases with increasing wavelength, OCT imaging in nontransparent tissues is possible using longer near-infrared wavelengths. In most tissues, imaging depths of 2–3 mm can be achieved using a system detection sensitivity of 100 to 110 dB. Imaging studies have been performed in a wide range of biological, medical, and surgical specialties including developmental biology, cardiology, gastroenterology, urology, and neurosurgery. High-resolution OCT using short coherence length, short pulsed light sources has also been demonstrated and axial resolutions less than 2 μm have been achieved. High-speed real-time OCT at image acquisition rates of 4 to 8 frames per second have also been demonstrated. OCT has been extended to perform Doppler imaging of blood flow and birefringence imaging to investigate tissue injury. Different imaging delivery systems including transverse imaging catheters and forward imaging devices have been developed to enable internal body OCT imaging. Most recently, an OCT catheter has been combined with endoscope-based delivery to perform *in vivo* imaging in animal models and human patients.

This chapter will provide an overview of the OCT technology, beginning with the basic principles of operation. Technological advancements over the last decade have enabled OCT to transition from laboratory- to clinical-based imaging. These enabling advancements will be discussed, followed by representative applications in biology, medicine, surgery, and materials.

Principles of Operation

OCT is based on optical ranging, the high-resolution, high dynamic range detection of backscattered light. In contrast to ultrasound, the velocity of light is extremely high. Therefore, the echo time delay of reflected light cannot be measured directly and interferometric detection techniques must be used. One method for measuring echo time delay is to use low coherence interferometry or optical coherence

domain reflectometry. Low-coherence interferometry was first developed for measuring reflections in fiber optics and optoelectronic devices.

The echo time delay of reflected light is measured by using a Michelson-type interferometer (Figure 1).

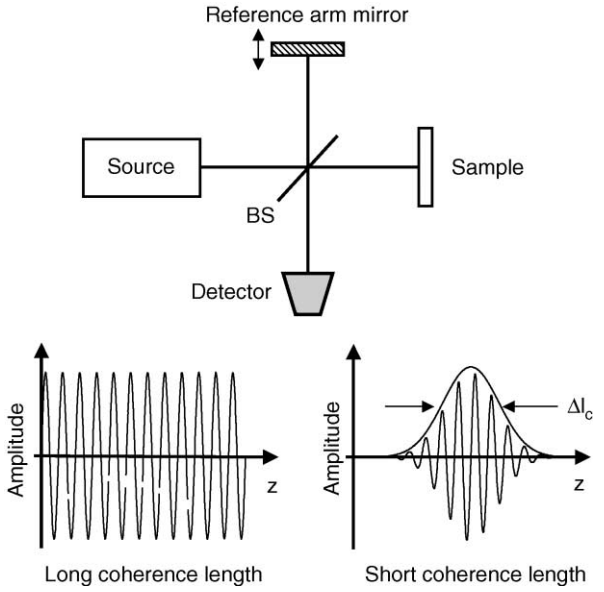

Figure 1 Schematic illustrating the concept of low-coherence interferometry. Using a short coherence-length light source and a Michelson-type interferometer, interference fringes are observed only when the path lengths of the two interferometer arms are matched to within the coherence length of the optical source. Abbreviations: BS, beam splitter; Δl_c, coherence length.

The light reflected from the specimen or sample is interfered with light that is reflected from a reference path of known path length. Interference of the light reflected from the sample arm and reference arm of the interferometer can occur only when the optical path lengths of the two arms match to within the coherence length of the optical source. As the reference arm optical path length is scanned, different echo delays of backscattered light from within the sample are measured. The interference signal is detected at the output port of the interferometer, electronically band-pass filtered, demodulated, digitized, and stored on a computer. The position of the incident beam on the specimen is typically scanned in the transverse direction and multiple axial measurements are performed. This generates a two-dimensional data array that represents the optical backscattering through a cross-sectional plane in the specimen (Figure 2). The logarithm of the backscatter intensity is then mapped to false-color or gray-scale and displayed as an OCT image. The interferometer in an OCT instrument can be implemented using a fiber optic coupler and beam-scanning can be performed with small mechanical galvanometers in order to yield a compact and robust system (Figure 3).

In contrast to conventional microscopy, the axial resolution in OCT images is determined by the coherence length of the light source. The axial point spread function of the OCT measurement as defined by the signal detected at the output of the

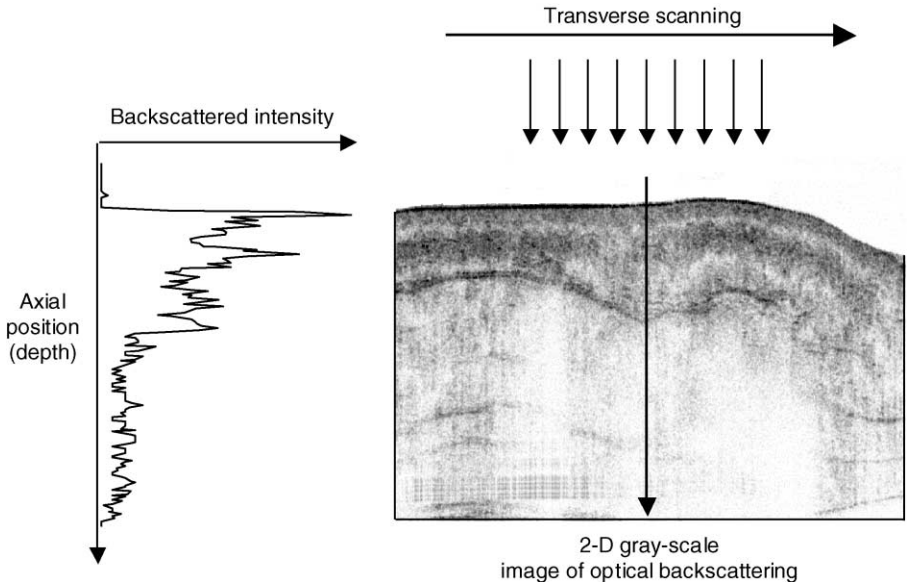

Figure 2 OCT image generation. The OCT image is typically acquired by performing axial measurements of optical backscatter at different transverse positions on the specimen and displaying the resulting two-dimensional data set as a gray-scale (or false-color) image.

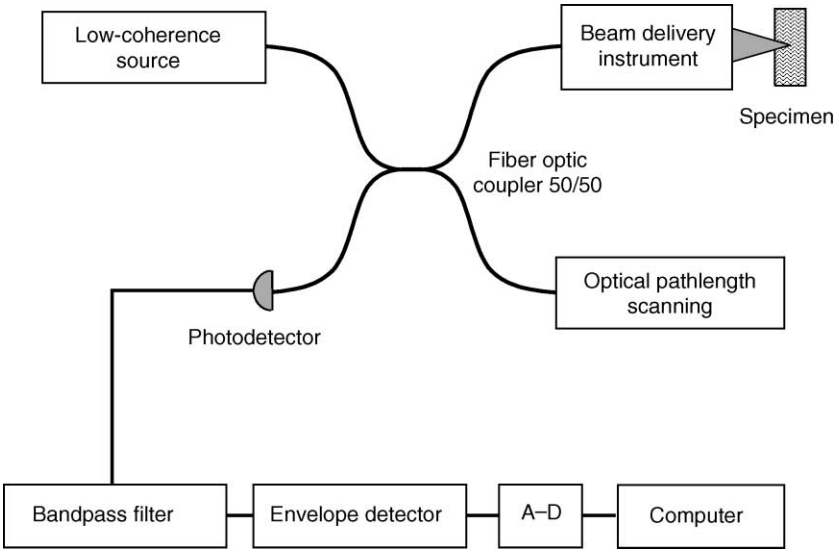

Figure 3 Schematic representation of an OCT system implemented using fiber optics. The Michelson interferometer is implemented using a fiber-optic coupler (beam splitter). The sample arm contains a beam-delivery instrument and the reference arm contains a mechanism for rapidly scanning the optical pathlength. The output of the interferometer is detected with a photodiode, filtered, demodulated, analog-to-digital (A–D) converted, and processed by a computer.

interferometer is the electric-field autocorrelation of the source. The coherence length of the light is the spatial width of the field autocorrelation and the envelope of the field autocorrelation is equivalent to the Fourier transform of its power spectrum. Thus, the width of the autocorrelation function, or the axial resolution, is inversely proportional to the width of the power spectrum. For a source with a Gaussian spectral distribution, the axial resolution Δz is given:

$$\Delta z = \frac{2\ln 2}{\pi} \cdot \frac{\lambda^2}{\Delta\lambda}$$

where Δz and $\Delta\lambda$ are the full-widths-at-half-maximum of the autocorrelation function and power spectrum respectively and λ is the source central wavelength. Figure 4 illustrates the dependence of the coherence length (axial resolution) on the bandwidth of the optical source. To achieve high axial resolution requires broad bandwidth optical sources. Resolution is also improved by using shorter wavelengths, however, shorter wavelengths are scattered and absorbed more in biological tissue.

The transverse resolution in an OCT imaging system is determined by the focused spot size in analogy with conventional microscopy and is given by:

$$\Delta x = \frac{4\lambda}{\pi} \cdot \frac{f}{d}$$

Where d is the spot size on the objective lens and f is its focal length. High transverse resolution can be obtained by using a large numerical aperture and

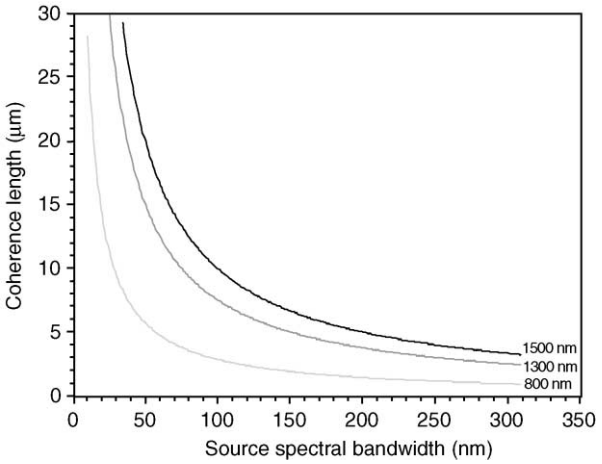

Figure 4 Dependence of coherence length (axial resolution) on the bandwidth of the optical source. Curves are shown for imaging wavelengths of 800 nm, 1300 nm, and 1500 nm. To achieve micron-scale resolution imaging, broad spectral bandwidths are necessary.

focusing the beam to a small spot size. The transverse resolution is also related to the depth of focus or the confocal parameter $2z_R$ (two times the Raleigh range).

$$2z_R = \frac{\pi\Delta x^2}{2\lambda}$$

Thus, increasing the transverse resolution results in a reduced depth of field. Typically, the confocal parameter or depth of focus is chosen to match the desired depth of imaging. Increased resolution may

also be obtained by using a higher numerical aperture lens or objective and spatially tracking the focus through the specimen.

Finally, the detection signal-to-noise is given by the optical power backscattered from the sample divided by the noise equivalent bandwidth:

$$\mathrm{SNR} = 10\log\left(\frac{\eta}{\hbar\omega}\frac{P_{\mathrm{SAM}}}{\mathrm{NEB}}\right)$$

Depending upon the desired signal to noise performance, incident powers of 5–10 mW are typically required for OCT imaging of 250–500 square pixel images at several frames per second. If lower data acquisition speeds or signal-to-noise can be tolerated, power requirements can be reduced accordingly.

Technological Developments

Since the inception of OCT in the early 1990s, there has been rapid technological developments aimed at improving the imaging resolution, acquisition rate, and methods for beam delivery to the tissue or sample. Investigators have also explored other imaging methods using the principles of OCT to extract information from the tissue or sample. Some of these methods have included acquiring optical Doppler signals from moving scatterers or structures, obtaining images based on the polarization state of the returned light, and extracting spectroscopic information based on the local absorption or scattering properties of the tissue.

Optical Sources / High-Resolution Imaging

The majority of OCT imaging systems to date have used superluminescent diodes (SLDs) as low coherence light sources. SLDs are manufactured with a similar structure to that of laser diodes, but commonly end facets are angle-cleaved to suppress lasing. These device structures do not support oscillation modes and generate output based on amplified spontaneous emission, resulting in emission spectra that are broader than laser diodes. SLDs are commercially available at a range of wavelengths including 800 nm, 1.3 μm, and 1.5 μm and are attractive because they are compact, have high efficiency, and low noise. However, output powers are typically limited to only a few milliwatts which limits fast real-time acquisition rates, and the available bandwidths are relatively narrow, permitting imaging with 10–15 micron resolution. Recent advances in short-pulse solid-state laser technology make these sources attractive for OCT imaging in research applications. Femtosecond solid-state lasers can generate tunable, low-coherence light at powers sufficient to permit high-speed OCT imaging. Short pulse generation has been achieved across the full wavelength range in titanium:sapphire ($Ti:Al_2O_3$) from 0.7 μm to 1.1 μm and over more limited tuning ranges near 1.3 μm and 1.5 μm in chromium: forsterite ($Cr^{4+}:Mg_2SiO_4$) and chromium:yttrium-aluminum-garnet (Cr^{4+}:YAG) lasers, respectively. OCT imaging with resolutions of 1 μm and 5 μm has been demonstrated at 800 nm and 1.3 μm respectively using $Ti:Al_2O_3$ and $Cr^{4+}:Mg_2SiO_4$ sources. More compact and convenient sources such as superluminescent fiber sources, are currently under investigation. The titanium:sapphire laser technology is routinely used in multi-photon microscopy applications for its high peak intensities to enable multi-photon absorption and subsequent emission of fluorescence from exogenous fluorescent contrast agents. Combined OCT and multi-photon microscopy has been used to provide complementary image data using a single optical source.

Fast Scanning

The short-pulse solid-state laser technology not only provides broad spectral bandwidths for high-resolution OCT imaging, but also higher output powers to enable fast real-time OCT imaging. Higher incident powers are required to maintain equivalent signal-to-noise ratios when scanning at a faster rate. Linearly translating a reference arm mirror is problematic at high rates and provides axial scan frequencies of approximately 100 Hz, depending on the mirror size and the translating galvanometer. Several investigators have utilized rotating glass cubes, piezoelectric modulators, and multi-pass optical cavities to increase axial scan rates while maintaining scan ranges of 1–2 mm. An optical delay based on the principles used in femtosecond pulse shaping has been demonstrated for OCT. This delay line spectrally disperses the reference arm beam with a grating. The dispersed beam is then focused by a lens on to a rotating mirror mounted on a galvanometer. The mirror, located in the Fourier-transform plane of the lens, imparts a wavelength-dependent phase shift on the light. Subsequently, when re-coupled back into the interferometer, this phase-shift is equivalent to a time-delay in the time domain. The use of high-speed resonant galvanometers has permitted axial scan rates as high as 8 kHz over scan ranges of several millimeters. Depending on the image pixel size (number of axial scans within each image), this scan rate can provide video-rate OCT imaging (30 frames per second). An example of high-speed *functional* OCT imaging is shown in Figure 5. Images of a

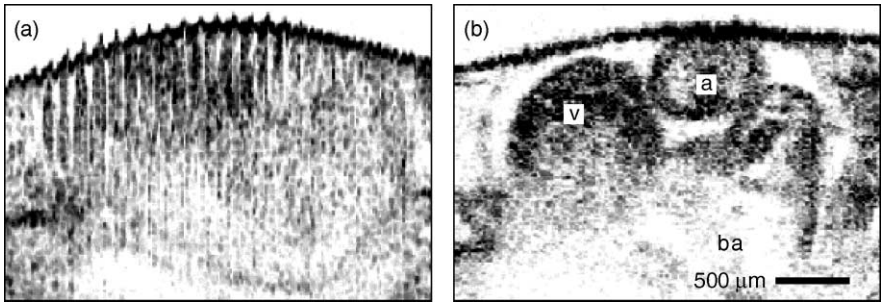

Figure 5 Comparison of slow and fast OCT imaging of a beating *Xenopus* (African frog) tadpole heart. The OCT image in (a) was acquired in 30 seconds and shows oscillations and blurring from the beating heart. The image on the right (b) was acquired in 250 ms (4 frames per second), fast enough to capture the anatomy of the heart with minimal motion artifacts. Abbreviations: a, atrium; ba, bulbous arteriosus; v, ventricle. (Images reprinted with permission from Boppart SA, Tearney GJ, Bouma BE, *et al.* (1997) Noninvasive assessment of the developing *Xenopus* cardiovascular system using optical coherence tomography. *Proceedings of the National Academy of Sciences* 94: 4256–4261.)

beating *Xenopus laevis* (African frog) tadpole were compared at slow (30 s per image) and at fast (250 ms per image) acquisition rates. Artifacts due to cardiac motion were present at slow acquisition rates, but were minimized with acquisition rates of 4 frames per second. Functional cardiac parameters could be measured and high-speed processes such as chamber and valve function could be visualized in real-time.

Depth-priority scanning, as described above, is performed by rapidly varying the optical delay in the reference arm and collecting a single axial scan before translating the beam laterally and repeating this depth-scanning. An alternative method for generating OCT images is with transverse-priority scanning. This is equivalent to optical sectioning in confocal and multi-photon microscopy. Three-dimensional OCT imaging using transverse-priority scanning can be obtained by stepping the position of the reference arm mirror after each *en face* image is acquired. The OCT images produced from transverse-priority scanning can be correlated with confocal or multi-photon microscopy images, which are acquired with the same scanning method. This method can also utilize higher numerical aperture objective lenses to provide high transverse resolutions since a large depth of focus is not needed as in depth-priority OCT scanning. The combination of OCT with high-numerical aperture objectives has been termed optical coherence microscopy.

Doppler Optical Coherence Tomography

Conventional OCT detects the amplitude of the optical backscatter versus position within the sample. Doppler OCT is a technique which has been applied to measuring fluid flow within small capillary tubes and *in vivo* vessels in the skin, retina, and heart of small animal models and humans. This technique is based on digitally sampling the interference fringes that are produced from a moving scatterer within the sample or specimen and determining the Doppler frequency shift in the signal due to the moving scatterer. Figure 6 illustrates two- and three-dimensional optical Doppler data for fluid flow through a cylindrical tube. A two-dimensional cross-sectional profile of fluid flow through a silicon tube with a 600 μm inner-diameter is plotted in Figure 6. The acquired data (points) closely match the predicted profile (line) for these tube dimensions. Below the plot, one method of obtaining a three-dimensional fluid flow profile is illustrated. While imaging the tube in cross-section, the fluid flow velocity was altered with a perfusion pump. The detection filter bandwidth of the OCT electronics served a windowing function, detecting only flow velocities with frequencies within the detection bandwidth. For an unknown flow profile, the center frequency of the detection filter can be shifted to map the flow velocities present within the sample.

Beam Delivery

The OCT imaging technology is modular in design and a variety of optical instruments can be used to deliver the OCT beam to the tissue or sample. Because OCT is fiber-optic based, single optical fibers can be used to deliver the OCT beam and collect the reflected light. The OCT technology can readily be integrated into existing optical instruments such as research and surgical microscopes, ophthalmic slit-lamp biomicroscopes, and hand-held imaging probes.

Imaging penetration is determined by the optical absorption and scattering properties of the tissue or specimen. The imaging penetration for OCT ranges from tens of millimeters for transparent tissues such as the eye to less than 3 mm in highly-scattering tissues such as skin. To image highly-scattering tissues deep within the body, novel beam-delivery

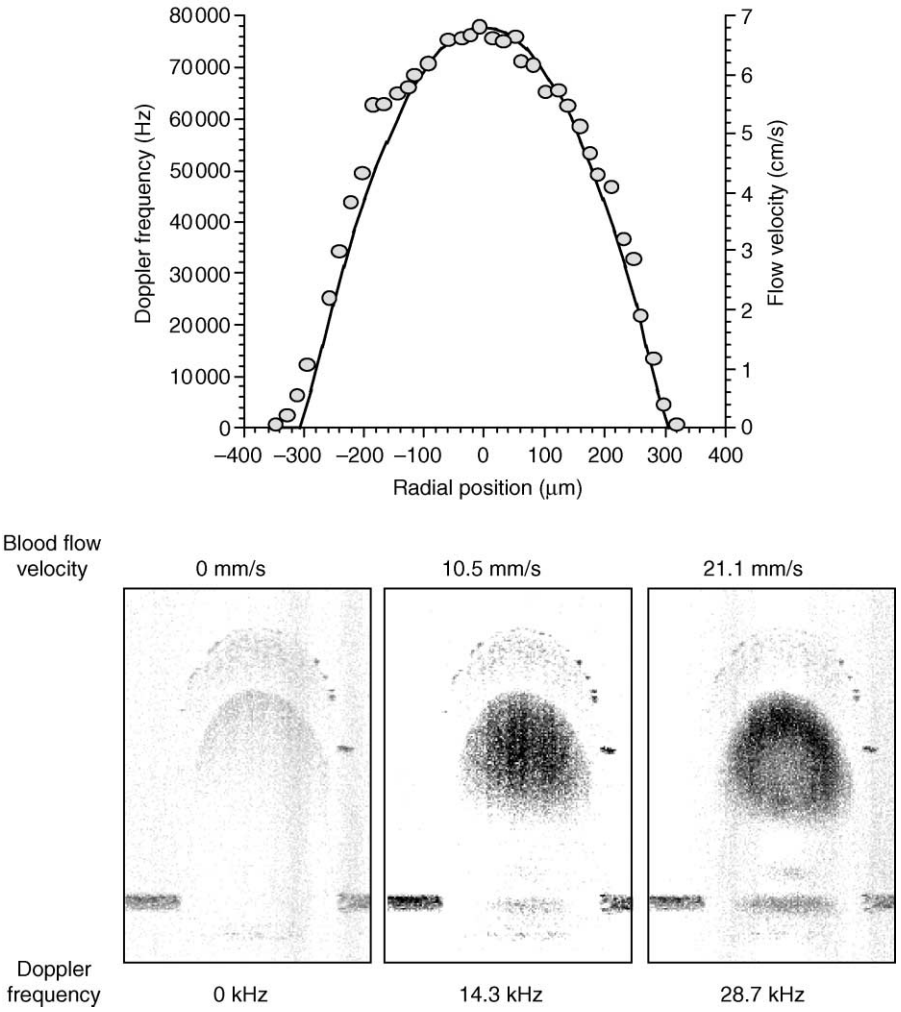

Figure 6 Doppler OCT. A two-dimensional plot of the fluid-flow velocity profile of flowing blood through a 600 μm inner-diameter tube is shown. Data points acquired using OCT closely follow the theoretical laminar flow profile (line). Two-dimensional Doppler OCT images of blood flow through the tube are shown below the plot. As fluid flow increases, only fluid-flow velocities within the bandwidth of the detection electronics are detected. This represents one method by which 3-D fluid flow can be imaged.

instruments have been developed to relay the OCT beam to the site of the tissue to be imaged. An OCT catheter has been developed for insertion into biological lumens such as the gastrointestinal tract. Used in conjunction with endoscopy, the 1 mm diameter catheter can be inserted through the working channel of the endoscope for simultaneous OCT and video imaging. Minimally-invasive surgical procedures utilize laparoscopes, which are long, thin, rigid optical instruments that permit video-based imaging within the abdominal cavity. Laparoscopic OCT imaging has been demonstrated by passing the OCT beam through the optical elements of a laparoscope. Deep solid-tissue imaging is possible with the use of fiber-needle probes. Small (400 μm diameter) needles housing a single optical fiber and micro-optic elements can be inserted into solid tissues and rotated to acquire OCT images. Recently, microfabricated micro-electro-optical-mechanical systems (MEOMS) technology has been used to miniaturize the OCT beam scan mechanism.

Applications

Developmental Biology

OCT has been demonstrated in the field of developmental biology as a method to perform high-resolution, high-speed imaging of developing morphology and function. Cellular-level imaging is possible, providing a non-invasive technique for visualizing cellular processes such as mitosis and migration. Imaging studies have been performed on several standard biological animal models commonly employed in developmental biology investigations including *Rana pipiens* (Leopard frog), *Xenopus laevis*

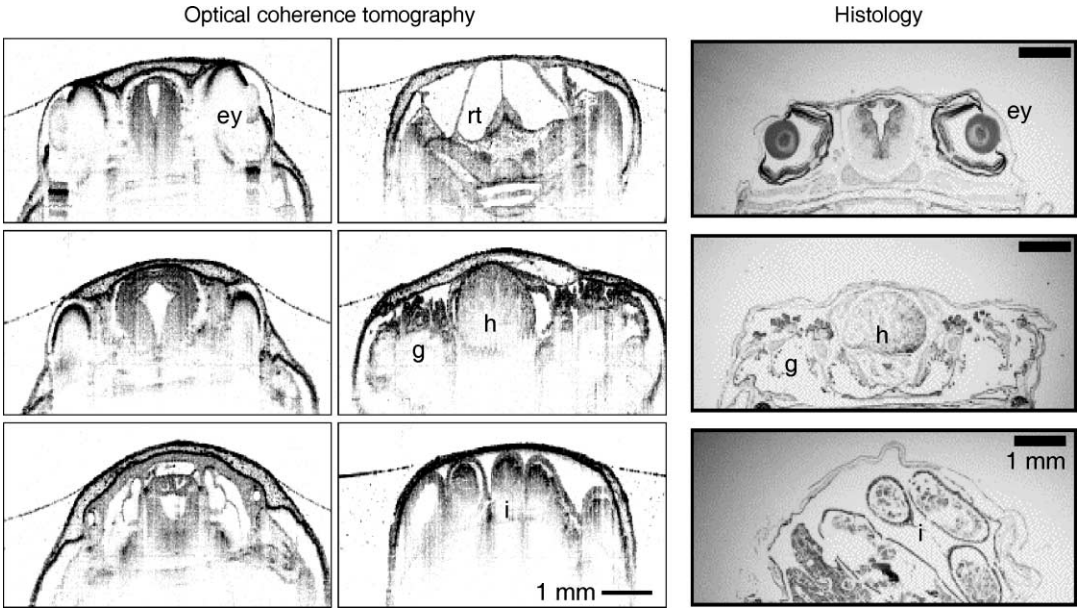

Figure 7 OCT images and corresponding histology of a Stage 49 (12 day) *Rana pipiens* (Leopard frog) tadpole. OCT images in the left and middle columns were acquired with the OCT beam incident from the dorsal and ventral sides of the specimen, respectively. The corresponding histology in the right column illustrates strong correlations between OCT images and the actual tissue morphology. Abbreviations: ey, eye; g, gills; h, heart; i, intestines; rt, respiratory tract. (Images reprinted with permission from Boppart SA, Brezinski ME, Bouma BE, *et al.* (1996) Investigation of developing embryonic morphology using optical coherence tomography. *Dev. Biol.* 177: 54–64.)

(African frog), and *Brachydanio rerio* (zebrafish) embryos and eggs, and the murine (mouse) model.

A series of cross-sectional images acquired *in vitro* from the dorsal and ventral sides of a Stage 49 (12 day) *Rana pipiens* (Leopard frog) tadpole is shown in Figure 7. Features of internal architectural morphology are clearly visible in the images. The image of the eye differentiates structures corresponding to the cornea, lens, and iris. Internal morphology not accessible in one orientation due to the specimen size or shadowing effects can be imaged by reorienting the specimen and scanning in the same cross sectional image plane. With the OCT beam incident on the ventral side, images of the respiratory tract, ventricle of the heart, internal gills, and gastrointestinal tract were acquired.

These images can be compared with corresponding histology (Figure 7). Histological images are acquired by euthanizing the specimen, immersing the specimen in a chemical fixative, and physically sectioning thin (2–5 micron-thick) slices using a microtome. The slices are placed on a microscope slide, selectively stained to highlight particular features, and viewed with light microscopy. The correlations between OCT and histology images are strong, suggesting that OCT images can accurately represent the *in vivo* specimen morphology. The potential exists to repeatedly image specimens to quantify organo- and morphogenesis throughout development. Technologies such as OCT are likely to become increasingly important in functional genomics, relating genetic features to the morphology and function in living specimens.

OCT images represent the optical backscatter intensity from regions within the tissue or sample. Because OCT relies on the inherent optical scattering changes to produce imaging contrast, no exogenous contrast agents or fluorophores are necessary. This permits long-term sequential imaging of development *in vivo* without loss of specimen viability. Repeated images of a developing zebrafish embryo within its egg beginning immediately after fertilization and up until hatching have been demonstrated without loss of specimen viability or without developmental abnormalities. In this example, the zebrafish egg and embryo were semi-transparent and the use of OCT significantly complemented observations made using light microscopy. By imaging subtle differences in backscattering intensity, interfacial structural layers millimeters deep within specimens can be clearly delineated.

Previous OCT images have characterized morphological features within biological specimens. These structures are static even though they may have been acquired from *in vivo* specimens. *In vivo* imaging in living specimens, particularly in larger organisms and

for medical diagnostic applications, must be performed at high speeds to eliminate motion artifacts within the images. Functional OCT imaging is the quantification of *in vivo* images which yield information characterizing the functional properties of the organ system or organism. High speed OCT permits both the positioning and manipulation of specimens as well as imaging in real time and is a powerful technology for functional imaging in developmental biology animal models.

Studies investigating normal and abnormal cardiac development have been frequently limited by an inability to access cardiovascular function within the intact organism. OCT has been demonstrated for the high-resolution assessment of structure and function in the developing *Xenopus laevis* (African frog) cardiovascular system (Figure 5). The morphology of the *in vivo* cardiac chambers is clearly delineated. Image acquisition rates are fast enough to capture the cardiac chambers in mid-cycle. With this capability, images can be acquired at various times during the cardiac cycle. These frames can be displayed in real-time to produce a movie illustrating the dynamic, functional behavior of the developing heart. OCT, unlike technologies such as computed tomography and magnetic resonance imaging, provides high-speed *in vivo* imaging, allowing quantitative dynamic activity, such as ventricular ejection fraction, to be assessed.

Cellular Imaging

Although previous studies have demonstrated *in vivo* OCT imaging of tissue morphology, most have imaged tissue at $\sim 10-15\ \mu m$ resolutions, which does not allow differentiation of cellular structure. The ability of OCT to identify the mitotic activity, the nuclear-to-cytoplasmic ratio, and the migration of cells has the potential to not only impact the fields of cell and developmental biology, but also impact medical and surgical disciplines for the early diagnostics of disease such as cancer.

The *Xenopus laevis* (African frog) tadpole has been used to demonstrate the feasibility of OCT for high-resolution *in vivo* cellular and subcellular imaging. Many of the cells in this common developmental biology animal model are rapidly dividing and migrating during the early growth stages of the tadpole, providing an opportunity to image dynamic cellular processes. Three-dimensional volumes of high-resolution OCT data have been acquired from these specimens throughout development. From this 3-D data set, cells undergoing division were identified and tracked in three dimensions. In a similar manner, 3-D data sets were acquired to track single melanocytes (neural crest cells) as they migrated through the living specimens. The ability of OCT to characterize cellular processes such as mitosis and migration not only are of interest in cell and developmental biology, but also have relevance for cancer diagnostics and tumor metastasis.

An example of cellular-level OCT imaging in these specimens is shown in Figure 8. This composite image (0.83×1 mm, 1800×1000 pixels) was acquired using a titanium:sapphire laser with a broad bandwidth (~ 260 nm). The axial and transverse resolution in this image is 1 μm and 5 μm, respectively (see Figure 4). Because the high transverse resolution reduced the depth-of-focus to 49 μm, separate OCT images were first acquired with the focus at different depths within the specimen. These images were then assembled to produce the composite image shown in Figure 8. This type of image construction is similar to C-mode ultrasound. Cellular features including cell membranes, nuclei, and nuclear morphology are clearly observed.

Medicine – Imaging Barrett's Esophagus

OCT performs *in situ* imaging and has the potential to be used as a screening technique of early pathological changes in patients. OCT imaging has the potential to be a general diagnostic in many organ systems,

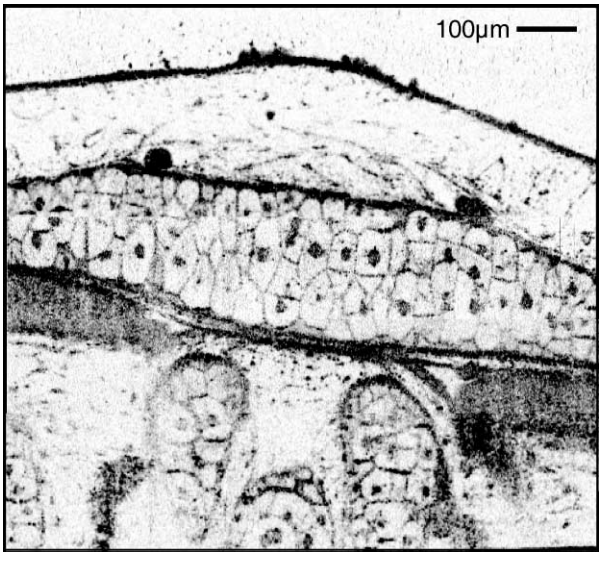

Figure 8 Cellular-level OCT imaging using a broad bandwidth titanium:sapphire laser. Axial and transverse image resolutions are 1 μm and 5 μm, respectively, enabling the visualization of cell membranes, nuclear morphology, and sub-cellular organelles. Cellular processes such as mitosis and migration can be visualized in real-time in living specimens. (Image reprinted with permission from Drexler W, Morgner U, Kartner FX, *et al.* (1999) *In vivo* ultrahigh resolution optical coherence tomography. *Optics Letters* 24: 1221–1223.)

particularly where current methods of screening by excisional biopsy are limited. Barrett's esophagus is a condition where the cells of the distal esophagus undergo a metaplastic change, resembling cells of the lower gastrointestinal tract. This condition is believed to be caused by chronic gastroesophageal reflux. Several studies have demonstrated that Barrett's esophagus is associated with a 30–125 times increased risk of developing adenocarcinoma. For this reason, endoscopic surveillance of Barrett's epithelium every 12–18 months is recommended. Endoscopic screening currently involves random four-quadrant biopsies every 1–2 cm along the length of suspect mucosa. However, excisional biopsy is prone to sampling errors and small foci of carcinoma or dysplasia may be missed. Because of the imprecision and high cost associated with screening, new methods are being developed to assess patients at increased risk. Endoscopic ultrasound catheters have been used for imaging the gastrointestinal tract with 50–100 μm resolution. However, these resolutions are insufficient to resolve early epithelial changes that occur in Barrett's esophagus and the pre-malignant changes that lead to adenocarcinoma of the esophagus.

The ability of OCT to differentiate normal and pathologic tissue is a central question being addressed by many research groups. Comparisons with histology show good correlations between OCT images and histological findings. The image resolution of conventional OCT (10–15 μm) is sufficient to differentiate architectural but not cellular morphology. Still, endoscopic OCT resolution can differentiate normal from Barrett's epithelium in real-time based on differences in epithelial architecture. Crypt- and gland-like structures that disrupt the relatively uniform layers of squamous epithelium can be readily identified, enabling differentiation between normal and Barrett's epithelium (Figure 9). The ability to differentiate normal from Barrett's epithelium suggests that the OCT technology could be used for screening applications.

Oncology – Identifying Tumors and Tumor Margins

OCT has been used to differentiate between the morphological structure of normal and cancerous tissue for a wide-range of tumors. The use of OCT to identify tumors and tumor margins *in situ* will represent a significant advancement for medical or image-guided surgical applications. OCT has been demonstrated for the detection of brain tumors and their margins with normal brain parenchyma, suggesting a role for guiding surgical resection. A hand-held surgical imaging probe was constructed for this application. The compact and portable probe permits OCT imaging within the surgical field while

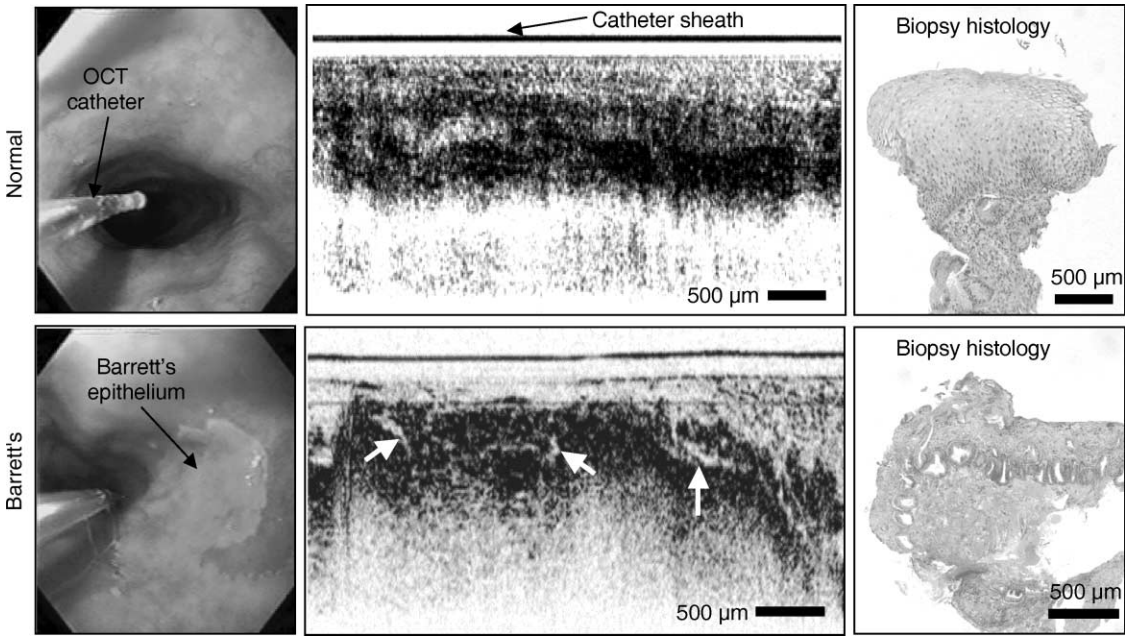

Figure 9 Endoscopic OCT imaging in humans. An OCT catheter was inserted down the working channel of an endoscope. Guided by video imaging, regions of normal and Barrett's esophagus were imaged. Corresponding biopsy histology is shown. OCT can identify Barrett's esophagus by the presence of gland- and crypt-like structures (arrows). (Images reprinted with permission from Li XD, Boppart SA, Van Dam J, *et al.* (2000) Optical coherence tomography: advanced technology for the endoscopic imaging of Barrett's esophagus. *Endoscopy* 32: 921–930.)

the OCT instrument can be remotely located in the surgical suite.

Figure 10 shows a specimen of outer human cerebral cortex with metastatic melanoma. The OCT images in Figure 10a,b were acquired through the tumor. These original images were threshold segmented to identify regions of high backscatter within the tumor. The original images were then overlaid with the segmented data and are shown in Figure 10c,d. The OCT images show increased optical backscattering in the region of the larger tumor (arrows). Smaller tumor lesions also appear within the image (arrows). A shadowing effect is observed below each tumor site due to the increased optical backscatter and the subsequent loss of optical power penetrating beneath the tumor. In Figure 10a,c, the boundary of the tumor can be identified. In Figure 10b,d, the tumor is identified below the surface of normal cortex. The histology in Figure 10e,f confirms the presence and relative size of the tumor.

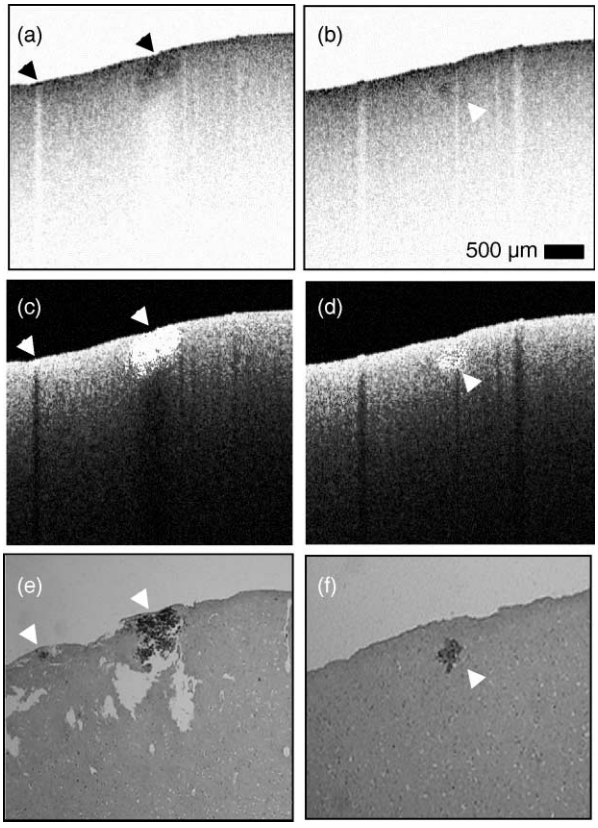

Figure 10 Cancer diagnostics. OCT imaging was used to image metastatic melanoma in an *ex vivo* specimen of human cortex (brain). Raw OCT images (a,b) were threshold-segmented (c,d) to highlight regions of increased optical backscatter and to identify tumor margins. OCT images correlate well with histological findings (e,f). (Images reprinted from Boppart SA, Brezinski ME, Pitris C and Fujimoto JG (1998) Optical coherence tomography for neurosurgical imaging of human intracortical melanoma. *Neurosurgery* 43: 834–841, with permission from Lippincott Williams and Wilkins.)

The image resolutions used to acquire the images in Figure 10 were as high as 16 μm, higher than any current ultrasound, CT, or MRI intraoperative imaging technique. This allowed the tumor-cortex interface and the extent of tumor below the surface to be defined with high resolution. At higher imaging resolutions, it may be possible to image individual tumor cells which have migrated away from the central tumor. OCT represents a new high-resolution optical imaging technology that has the potential for identifying tumors and tumor margins on the micron scale and in real-time. OCT offers imaging performance not achievable with current imaging modalities and may contribute significantly toward the surgical resection of neoplasms.

Image-Guided Surgery

The repair of vessels and nerves is necessary to restore function following traumatic injury. Although the repair of these sensitive structures is performed with the aid of surgical microscopes and loupes to magnify the surgical field, surgeons are limited to the *en face* view that they provide. A technique capable of subsurface, three-dimensional, micron-scale imaging in real-time would permit the intraoperative monitoring of microsurgical procedures. The capabilities of OCT for the intraoperative assessment of microsurgical procedures have been demonstrated. High-speed OCT imaging was integrated with a surgical microscope to performed micron-scale three-dimensional imaging on microsurgical specimens.

OCT has been used to image *in vitro* peripheral nerves and identify individual fascicles. Longitudinal tracking of the spatial orientation of rabbit peripheral nerve fascicles is demonstrated in Figure 11. Representative cross-sectional images of the peripheral nerve are shown in Figure 11a–d. For each slice, one fascicle was manually segmented, colored white, and tracked through the acquired volume of data. Forty images at 100 μm spacing were assembled for the 3-D projections shown in Figure 11e,f. The horizontally- and vertically-rotated projections of the peripheral nerve dramatically reveal the twisted path of the segmented fascicle along the longitudinal axis of the nerve. In addition, a branch in an unsegmented fascicle is observed in Figure 11f. The use of OCT to acquire multiple cross-sectional images and three-dimensionally reconstruct the peripheral nerve offers the opportunity to determine the relative diameters of individual fascicles and to longitudinally track their spatial orientation. OCT may also be useful at identifying and grading the degree of injury in nerves during surgical repair. These results have shown how 2-D OCT images and 3-D OCT projections can

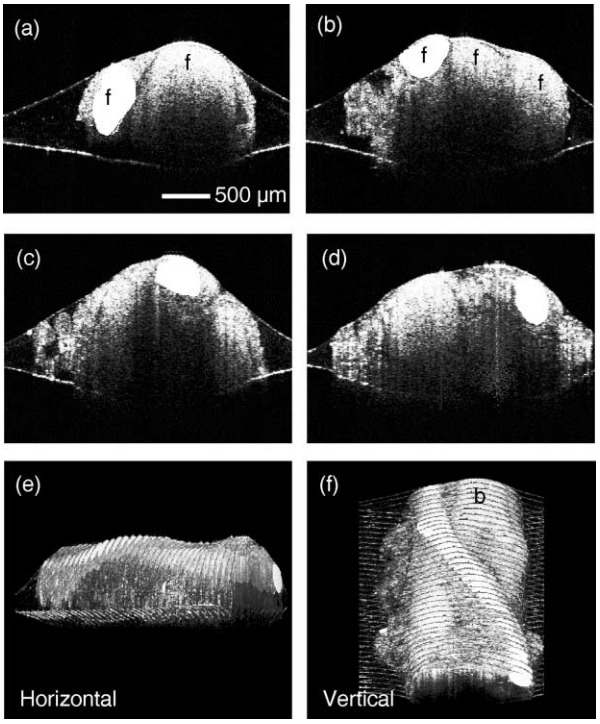

Figure 11 OCT image-guided microsurgery. Multiple cross-sectional OCT images were acquired through a resected rabbit peripheral nerve (a–d). A single nerve fascicle (f) was identified and segmented longitudinally along the length of the nerve. Three-dimensional reconstruction projections of the nerve in (e,f) reveal the tortuous path of the segmented fascicle as well as reveal a bifurcation (b). Intraoperative OCT can guide surgical repair and potentially identify regions of damaged tissue. (Images reprinted from Boppart SA, Bouma BE, Pitris C, *et al.* (1998) Intraoperative assessment of microsurgery with three-dimensional optical coherence tomography. *Radiology* 208: 81–86, with permission from the Radiology Society of North America.)

provide diagnostic feedback to assess microsurgical anastomoses. This previously unavailable diagnostic ability offers the potential to directly impact and improve patient outcome by incorporating high-speed, high-resolution intraoperative image-guidance during microsurgical procedures.

Surgical intervention requires visualization to identify tissue morphology, precision to avoid sensitive tissue structures, and continuous feedback to monitor the extent of the intervention. OCT may provide the technological advancements to improve the operative procedure. The feasibility of OCT to perform image-guided surgical intervention has been investigated. OCT has been used to monitor laser ablation therapy in real-time and may enable more precise control of laser delivery. An argon-laser ablation sequence of fresh *ex vivo* rat rectus abdominis muscle is shown in Figure 12. A pair of blood-filled vessels were located 1.5 mm below the tissue surface and centered within the OCT image. Because blood has a higher absorption coefficient than muscle at the 514 nm argon laser wavelength, coagulation and thermal heating of the blood occurred prior to thermal damage to the overlying tissue. The accompanying histology reveals both the thermally-damaged overlying tissue and coagulated blood present within the vessel pair.

These examples demonstrate the use of OCT for guiding and monitoring surgical intervention. The laser is only a representative interventional surgical technique for a wide range of instruments and techniques including scalpels, electrosurgery, radio-frequency, microwaves, and ultrasound ablation. OCT imaging was performed at 8 frames per second, fast enough to capture dynamic changes in the optical properties of the tissue during thermal ablation. These image sequences provided interesting insight into ablation mechanisms for a variety of tissue types. OCT can monitor the extent of thermal injury below the surface of the tissue by imaging the changes in optical backscatter. OCT imaging can therefore provide empiric information for dosimetry to minimize the extent of collateral injury. The use of OCT for guiding surgical interventions has the potential to improve intraoperative monitoring and more effectively control interventional procedures.

Materials

While the majority of OCT applications have been in the fields of biology and medicine. OCT has also been demonstrated in the non-biological areas of materials investigation, optical data storage, and microfluidic devices. The highly-scattering or reflecting optical properties of many materials prohibits deep imaging penetration using OCT. Many material defects, however, originate near the surface or at interfacial boundaries, making the use of OCT a possibility for inspection and quality control. OCT has been used to identify subsurface defects in ceramics and polymer composites. The optical ranging capabilities of OCT through scattering materials has been utilized for increasing the data storage capacity by assembling multiple layers of optically-accessible data.

The advancement of microfabrication techniques has led to increasingly complex microfluidic and bioMEM (biological micro-electro-mechanical) systems. Microstructures within microfluidic systems range from 10–1000 μm, within both the imaging depth and resolution of OCT. In addition, microfluidic systems are typically fabricated from transparent or semi-transparent substrates, facilitating imaging penetration to deeper three-dimensional features.

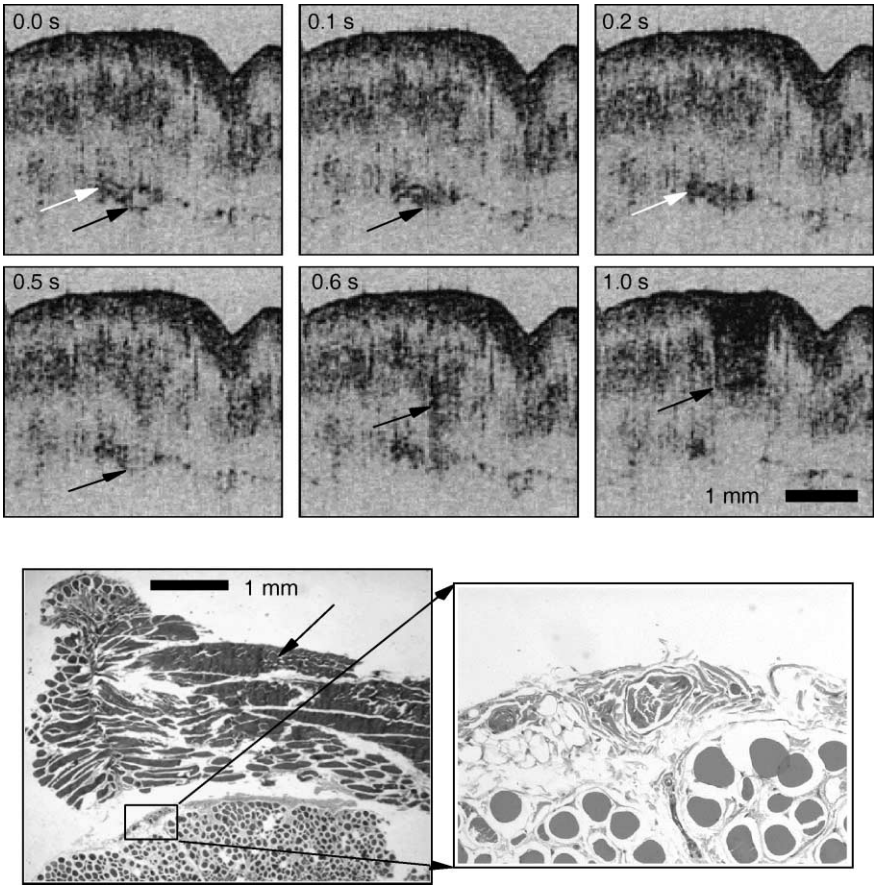

Figure 12 OCT image-guided laser ablation. High-speed OCT image sequence of argon-laser ablation of blood vessels in *ex vivo* rat muscle tissue. Thermal heating within the blood vessels (arrows, 0.0–0.5 s) induces coagulation prior to injury to superficial muscle tissue (0.6–1.0 s). Accompanying histology shows coagulated blood within the vessels.

OCT is not only capable of imaging three-dimensional microstructures at micron-scale resolutions, but is also capable of obtaining dynamic functional data from microfluidic systems. Microfluidic devices made from polymeric materials are attractive since they provide flexibility in the design of the channels, can be manufactured in large volumes, and are mostly bio-compatible. A three-dimensional imaging technique, such as OCT, will be instrumental in the analysis of these devices and the monitoring of device performance.

Conclusions

The capabilities of OCT offer a unique and informative means of imaging biological specimens and non-biological samples. The non-contact nature of OCT and the use of low-power near-infrared radiation for imaging causes few harmful effects on living cells or damage to materials. OCT imaging does not require the addition of fluorophores, dyes, or stains in order to improve contrast in images. Instead, OCT relies on the inherent optical contrast generated from variations in optical scattering and index of refraction. These factors permit the use of OCT for extended imaging over the course of hours, days, or weeks. OCT permits the cross-sectional imaging of tissue and samples and enables *in vivo* structure to be visualized in opaque specimens or in specimens too large for high-resolution confocal or light microscopy.

Imaging at cellular and subcellular resolutions with OCT is an important area of ongoing research. The *Xenopus* (African frog) developmental animal model has been commonly used because its care and handling are relatively simple while allowing cells with a high mitotic index to be assessed. Many of the cells observed were as large as 100 μm in diameter, but ranged in size down to a few microns, below the resolution of most OCT systems. Imaging human cells *in vivo* remains a challenge since differentiated human cells are 10 to 20 microns in size, too small for most OCT systems. With further advances in OCT technology, improved discrimination and

imaging of more detailed structures should be possible. New laser sources at other wavelengths in the near-infrared can enhance tissue contrast as well as potentially provide functional information since tissue scattering and absorbance properties in specimens are wavelength dependent. Short coherence length short pulse laser sources have been used to achieve higher axial resolutions on the order of 1 to 3 microns. Unfortunately, unlike superluminescent diode source, these high-speed and high-resolution systems utilize femtosecond lasers that are relatively complex and costly. Developing compact and portable optical sources at near-infrared wavelengths, broad spectral bandwidths, and high output powers is an area of active research.

Optical coherence tomography provides high-resolution morphological, functional, and cellular information of biological, medical, and material specimens and samples. OCT represents a multifunctional investigative tool that not only complements many of the existing imaging technologies available today, but also is poised to become a major optical imaging modality.

List of Units and Nomenclature

$Cr^{4+}:Mg_2SiO_4$	chromium:forsterite
Cr^{4+}:YAG	chromium:yttrium-aluminum-garnet
CT	computed tomography
d	beam diameter
f	focal length
MRI	magnetic resonance imaging

Introduction

'Tomos' means section, in Greek. A tomogram is a sectional image of the internal structure of a three-dimensional object. One of the challenges for tomographic imaging of biological tissue using visible or near-infrared light is tissue optical scattering. When photons propagate inside a tissue, they undergo multiple scattering. The mean free path of photons in the skin, for example, is 5 μm. If one focuses the light 1 mm below the skin surface, most photons undergo multiple scattering and never reach the target point. Less than one out of a million photons will be able to reach the target, undergo a single backscattering, and return to the detector (Figure 1). Most photons that are backscattered and reach the detector are multiple scattered photons that carry little information on the target point. The challenge for tomographic imaging of tissues is to separate the single backscattered photons, that carry information about the target point, from multiple scattered photons.

Several optical tomography techniques have been developed. Each uses different techniques to discriminate the multiple scattering photons from the minimally scattered photons for imaging constructions. The confocal microscope, for example, uses a spatial filtering technique to reject multiple scattering photons because multiple scattered photons are more spread out in their angular distribution than the minimally scattered photons. Time-of-flight imaging uses a time gating technique to discriminate diffuse photons because single backscattered photons arrive earlier than diffuse photons. Optical coherence tomography (OCT) uses coherent gating to discriminate single scattered photons from multiple scattered photons. These gating techniques provide good discrimination of minimally scattered photons from multiple scattered photons and can form high-resolution sectional images, albeit with a limited imaging depth. Diffuse photons can propagate deep into the tissue and these photons can also be used for optical tomography. If a modulated photon density wave is propagated inside the tissue, the scattering and absorption properties of the tissue will modulate the phase and amplitude of the photon density wave. However, the resolution of optical tomography, based on diffuse photons, is usually much lower than that of the tomography constructed from single or minimally scattered photons. Three of the most important parameters for optical tomography are contrast, spatial resolution, and image depth.

Most optical tomography uses absorption, scattering, and fluorescent properties of materials as contrast. OCT, for example, uses variations in tissue scattering as contrast for tomographic imaging. However, in many instances, and especially during the early stages of disease, the change in tissue scattering properties between normal and diseased tissues is small and difficult to measure. One of the great challenges for extending applications of OCT is to find more contrast mechanisms that can provide physiological information in addition to morphological structure. This article will focus on optical tomography technologies that use nonconventional contrast mechanisms to obtain tomographic images. These include optical Doppler tomography (ODT), optical polarization tomography, and optical second-harmonic tomography. These optical tomography technologies are extensions of OCT with contrast mechanisms that can provide physiological information, in addition to morphological structure. ODT, also known as Doppler OCT, combines the Doppler principle with OCT to obtain high-resolution tomographic images of tissue structure and blood flow simultaneously. Optical polarization tomography, also known as polarization sensitive OCT (PS-OCT), combines polarization sensitive

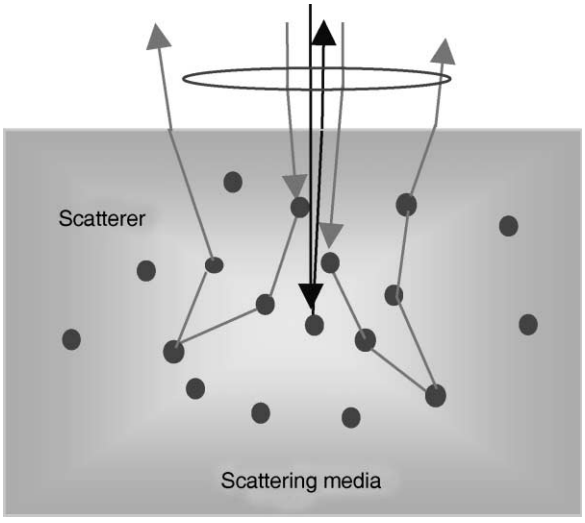

Figure 1 Optical imaging in scattering media.

detection with OCT, to determine tissue birefringence. Optical second-harmonic tomography, also known as second-harmonic optical coherence tomography (SH-OCT), combines second-harmonic generation (SHG) with coherence gating to obtain images with molecular contrast. These functional extensions of OCT provide clinically important information on tissue physiology, such as tissue blood perfusion, oxygen saturation, hemodynamics, and structural remodeling. Each provides several potential clinical applications, such as vasoactive drug screening, tissue viability and burn depth determination, tumor angiogenesis studies, tumor diagnosis, bleeding ulcer management, and ocular pathology evaluation.

Optical Doppler Tomography

ODT combines the Doppler principle with OCT to obtain high-resolution tomographic images of static and moving constituents in high scattering media. When light backscattered from a moving particle interferes with the reference beam, a Doppler frequency shift (f_D) occurs in the interference fringe:

$$f_D = \frac{1}{2\pi}(\mathbf{k}_s - \mathbf{k}_i)\cdot\mathbf{v} \qquad [1]$$

where $\mathbf{k}_i$ and $\mathbf{k}_s$ are wavevectors of incoming and scattered light, respectively, and $\mathbf{v}$ is the velocity vector of the moving particle (Figure 2). Since ODT measures the backscattered light, assuming the angle between flow and sampling beam is θ, the Doppler shift equation is simplified to:

$$f_D = \frac{2V\cos\theta}{\lambda_0} \qquad [2]$$

where λ_0 is the vacuum center wavelength of the light source.

The optical system of ODT is similar to that of OCT. The primary difference is in signal processing. Figure 3 illustrates an ODT instrument that uses a fiber optic Michelson interferometer with a broadband light source. Light from a broadband partial coherence source is coupled into a fiber interferometer by a 2 × 2 fiber coupler and then split equally into reference and target arms of the interferometer. Light backscattered from the turbid sample is coupled back into the fiber and forms interference fringes with the light reflected from the reference arm. A rapid-scanning optical delay line is used for group delay and axial scanning. Because this delay line can decouple the group delay from the phase delay, an electro-optical phase modulator is introduced to produce a stable carrier frequency. The interference fringe intensity signal is amplified, bandpass filtered, and digitized with a high-speed analog-to-digital converter. The signal processing is carried out at the same time as data are transferred to the computer, and real-time display can be accomplished with the use of a digital signal processing board.

To understand the signal processing of ODT, let us look at the fringe signal due to the moving particles.

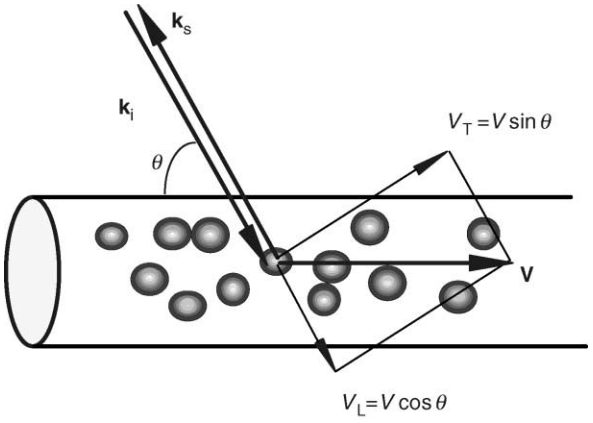

Figure 2 Schematic of flow direction and probe beam angle.

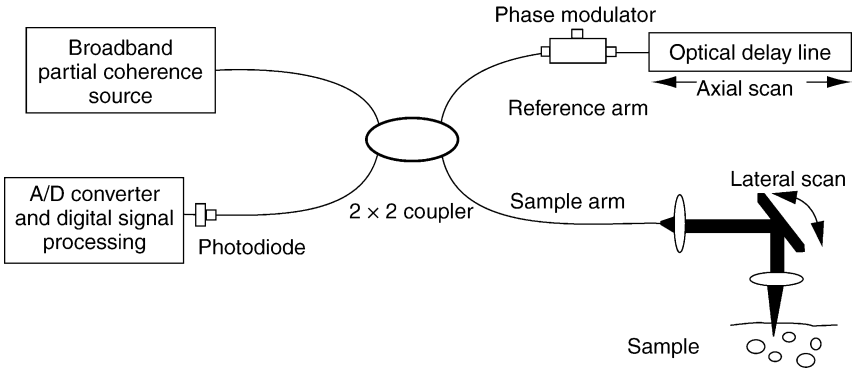

Figure 3 Schematic of ODT system consists of a fiber-based Michelson interferometer with a partially coherent light source.

If we denote $U(t)$ as a complex-valued analytic signal of a stochastic process representing the field amplitude emitted by a low coherent light source and $\bar{U}(\nu)$ as the corresponding spectral amplitude at optical frequency ν, the amplitude of a partially coherent source light coupled into the interferometer at time t, is written as a harmonic superposition:

$$U(t) = \int_0^\infty \bar{U}(\nu) e^{2\pi i \nu t} \, d\nu \quad [3]$$

Because the stochastic process of a partially coherent light source is stationary, the cross spectral density of $\bar{U}(\nu)$ satisfies:

$$\langle \bar{U}^*(\nu)\bar{U}(\nu')\rangle = S_0(\nu)\delta(\nu - \nu') \quad [4]$$

where $S_0(\nu)$ is the source power spectral density, and $\delta(\nu - \nu')$ is the Dirac delta function. Assuming that light couples equally into the reference arm and sample arm with spectral amplitude of $\bar{U}_0(\nu)$, the light coupled back to the detector from the reference, $\bar{U}_r(\nu)$, and sample, $\bar{U}_s(\nu)$, are:

$$\bar{U}_r(\nu) = e^{2\pi i \nu (2L_r + L_d)/c} K_r(\nu) e^{i\alpha_r} \bar{U}_0(\nu) \quad [5]$$

$$\bar{U}_s(\nu) = e^{2\pi i \nu (2L_s + L_d)/c} K_s(\nu) e^{i\alpha_s} \bar{U}_0(\nu) \quad [6]$$

where L_r and L_s are the optical pathlengths from the beamsplitter to the reference mirror and sample, respectively; L_d is the optical pathlength from the beamsplitter to the detector; and $K_r(\nu)e^{i\alpha_r(\nu)}$ and $K_s(\nu)e^{i\alpha_s(\nu)}$ are the amplitude reflection coefficients of light backscattered from the reference mirror and turbid sample, respectively.

The total power detected at the interferometer output is given by a time-average of the squared light amplitude:

$$P_d(\tau) = \langle |U_s(t) + U_r(t+\tau)|^2 \rangle \quad [7]$$

where τ is the depth scan time delay. Combining harmonic expansions for $U_s(t)$ and $U_r(t)$ and applying eqn [4] when calculating the time-average, the total power detected is a sum of three terms representing reference (I_r), sample (I_s), and the interference fringe intensity ($\Gamma_{ODT}(\tau)$):

$$\begin{aligned} P_d(\tau) &= \int_0^\infty \big(P_r(\nu) + P_s(\nu) + P_{ODT}(\nu)\big) d\nu \\ &= I_r + I_s + \Gamma_{ODT}(\tau) \end{aligned} \quad [8]$$

with

$$P_r(\nu) = S_0(\nu)|K_r(\nu)|^2 \quad [9]$$

$$P_s(\nu) = S_0(\nu)|K_s(\nu)|^2 \quad [10]$$

$$\begin{aligned} P_{ODT}(\nu) = 2S_0(\nu)K_r(\nu)K_s(\nu) \\ \times \cos\left[2\pi\nu(\Delta_d/c + \tau) + \alpha_s(\nu) - \alpha_r(\nu)\right] \end{aligned} \quad [11]$$

and

$$I_r = \int_0^\infty P_r(\nu) d\nu \quad [12]$$

$$I_s = \int_0^\infty P_s(\nu) d\nu \quad [13]$$

$$\Gamma_{ODT}(\tau) = \int_0^\infty P_{ODT}(\nu) d\nu \quad [14]$$

When there is a moving particle, light scattered from this particle is equivalent to a moving phase front; therefore, Δ_d in eqn [11] can be written as:

$$\Delta_d = \Delta + 2\bar{n}V_z t \quad [15]$$

where Δ is the optical pathlength difference between light in the sampling and reference arms; V_z is the velocity of a moving particle parallel to the probe beam; and $\bar{n}$ is the refractive index of flow media.

To simplify the computation, we assume α_s and α_r are constants over the source spectrum and can be neglected. The spectral domain fringe signal, $P_{ODT}(\nu)$, is simplified to:

$$\begin{aligned} P_{ODT}(\nu) = 2S_0(\nu)K_r(\nu)K_s(\nu) \\ \times \cos\left[2\pi\nu\left((\Delta + 2\bar{n}V_z t)/c + \tau\right)\right] \end{aligned} \quad [16]$$

The corresponding time domain signal, $\Gamma_{ODT}(\tau)$, is given by:

$$\begin{aligned} \Gamma_{ODT}(\tau) = 2\int_0^\infty S_0(\nu)K_r(\nu)K_s(\nu) \\ \times \cos\left[2\pi\nu\left((\Delta + 2\bar{n}V_z t)/c + \tau\right)\right] d\nu \end{aligned} \quad [17]$$

A comparison of eqns [16] and [17] shows that there is a Fourier transformation relation between spectral domain and time domain signals. Consequently, there are two methods to acquire the ODT signal: the time domain method and the spectral domain method.

In the time domain method, a delay line is incorporated in the reference arm to generate a delay. A spectrogram analysis or phase-resolved algorithm is then used to determine the Doppler frequency shift. In the spectral domain method, the reference mirror is fixed, and there is no depth scan ($\tau = 0$). The spectral domain fringe signal, $P_{ODT}(\nu)$, is obtained either by a spectrometer at the detection

arm, or by a frequency sweeping light source. The time domain signal, $\Gamma_{ODT}(\tau)$, is determined from the spectral domain signal by a Fourier transformation.

Spectrogram Method

The spectrogram method uses time–frequency analysis to calculate the Doppler shift. Signal processing algorithms to obtain structural and velocity images from recorded temporal interference fringe intensity using the spectrogram method, are illustrated in Figure 4.

The spectrogram is an estimate of the power spectrum of the temporal interference fringe intensity ($\Gamma_{ODT}(\tau_i, f_j)$) in the ith time delay window. The power spectrum of the temporal interference fringe at the ith pixel, corresponding to time delay τ_i in the structural and velocity images, is calculated by a short-time fast Fourier transformation (STFFT) or a wavelet transformation:

$$\hat{\Gamma}_{ODT}(\tau_i, f_m) = |\mathrm{STFFT}(f_m; \Gamma_{ODT}(\tau))|^2 \qquad [18]$$

where f_m is the discrete frequency value. A tomographic structural image is obtained by calculating the value of the power spectrum at the phase modulation frequency (f_0). Fluid flow velocity is determined from the Doppler frequency shift (f_D), which is the difference between the carrier frequency established by the optical phase modulation (f_0) and the centroid (f_c) of the measured power spectrum at the ith pixel:

$$V_{ODT}(i) = \frac{\lambda_0 f_D}{2\bar{n}\cos\theta} = \frac{\lambda_0(f_c - f_0)}{2\bar{n}\cos\theta} \qquad [19]$$

where we have assumed, $\mathbf{k}_s = -\mathbf{k}_i$ and θ is the angle between $\mathbf{k}_i$ and $\mathbf{v}$. The centroid of the measured power spectrum is determined by:

$$f_c = \sum_m f_m \hat{\Gamma}_{ODT}(\tau_i, f_m) \Big/ \sum_m \hat{\Gamma}_{ODT}(\tau_i, f_m) \qquad [20]$$

Figure 5 shows the *in vivo* structural and blood flow images from a chick chorioallantoic membrane. The lumen wall, chorion membrane, and yolk sac membrane are observed in structural image (a). In the velocity image (b), static regions ($V = 0$) appear dark, while blood flowing at different velocities appears as different brightnesses on the gray scale. The velocity profile taken from a horizontal cross-section passing through the center of the vessel is shown in (c).

Phase-Resolved ODT Method

Although spectrogram methods allow simultaneous imaging of *in vivo* tissue structure and flow velocity, the velocity sensitivity is limited for high-speed imaging. When STFFT or wavelet transformation is used to calculate flow velocity, the resolution is determined by the window size of the Fourier transformation for each pixel. The minimum detectable Doppler frequency shift, f_D, varies inversely with the STFFT window size. Because pixel acquisition time is proportional to the STFFT window size, the image frame rate is limited by velocity resolution. Furthermore, spatial resolution is also proportional to the STFFT window size. Therefore, a large STFFT window size increases velocity resolution while decreasing imaging speed and spatial resolution. This coupling between velocity sensitivity, spatial resolution, and imaging speed prevents the spectrogram method from achieving simultaneously both high imaging speed and high velocity sensitivity, which are essential for measuring flow in small blood vessels where flow velocity is low.

Phase-resolved ODT overcomes the compromise between velocity sensitivity and imaging speed by using the phase change between sequential scans to construct flow velocity images. The phase information of the fringe signal can be determined from the complex analytical signal $\tilde{\Gamma}(t)$, which is determined through analytic continuation of the measured interference fringe function, $\Gamma(t)$, using a Hilbert transformation:

$$\tilde{\Gamma}(t) = \Gamma(t) + \frac{i}{\pi} P \int_{-\infty}^{\infty} \frac{\Gamma(\tau)}{\tau - t}\, d\tau = A(t) e^{i\phi(t)} \qquad [21]$$

where P denotes the Cauchy principle value, i is the complex number, and $A(t)$ and $\phi(t)$ are amplitude and phase of $\tilde{\Gamma}(t)$, respectively. Because the interference signal $\Gamma(t)$ is quasi-monochromatic, the complex

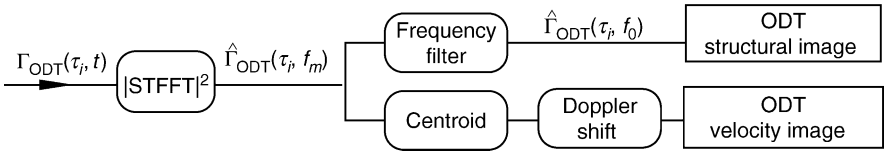

Figure 4 Signal processing algorithms for ODT structural and velocity images.

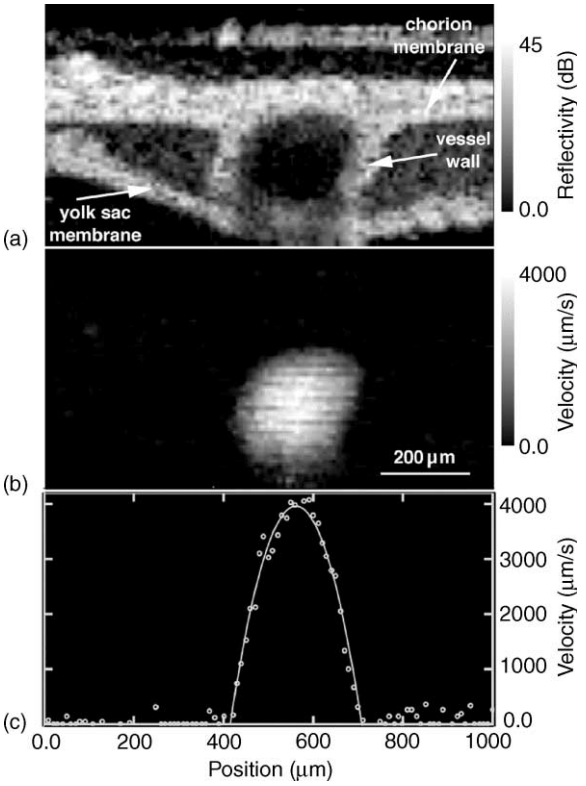

Figure 5 ODT images of *in vivo* blood flow in a CAM vein. (a) Structural image, (b) velocity image, and (c) velocity profile taken from a horizontal cross-section passing through the center of the vein, where the open circles are experimental data and the solid line is a parabolic fit. Reproduced with permission from Chen Z, MilnerTE, Srinivas S, Wang XJ, Malekafzali A, van Gemert MJC and Nelson JS (1997) Noninvasive imaging of *in vivo* blood flow velocity using optical doppler tomography. *Optics Letters* 22: 1119–1121.

analytical signal can be determined by:

$$\tilde{\Gamma}(t) = 2\int_0^{\infty}\int_0^{\tau}\Gamma(t')\exp(-2\pi i\nu t')\mathrm{d}t' \times \exp(2\pi i\nu t)\mathrm{d}\nu \qquad [22]$$

where τ is the time duration of the fringe signal in each axial scan.

The Doppler frequency shift (f_n) at nth pixel in the axial direction is determined from the average phase shift between sequential A-scans. This can be accomplished by calculating the phase change of sequential scans from the individual analytical fringe signal:

$$f_n = \frac{\Delta\phi}{2\pi T} = \frac{1}{2\pi T}\sum_{m=(n-1)M}^{nM}\sum_{j=1}^{N}\left[\tan^{-1}\left(\frac{\mathrm{Im}\tilde{\Gamma}_{j+1}(t_m)}{\mathrm{Re}\tilde{\Gamma}_{j+1}(t_m)}\right) - \tan^{-1}\left(\frac{\mathrm{Im}\tilde{\Gamma}_{j}(t_m)}{\mathrm{Re}\tilde{\Gamma}_{j}(t_m)}\right)\right] \qquad [23]$$

Alternatively, the phase change can also be calculated by the cross-correlation method:

$$f_n = \frac{1}{2\pi T}\tan^{-1}\left(\frac{\mathrm{Im}\left[\sum_{m=(n-1)M}^{nM}\sum_{j=1}^{N}\tilde{\Gamma}_j(t_m)\cdot\tilde{\Gamma}^*_{j+1}(t_m)\right]}{\mathrm{Re}\left[\sum_{m=(n-1)M}^{nM}\sum_{j=1}^{N}\tilde{\Gamma}_j(t_m)\cdot\tilde{\Gamma}^*_{j+1}(t_m)\right]}\right) \qquad [24]$$

where $\tilde{\Gamma}_j(t_m)$ and $\tilde{\Gamma}^*_j(t_m)$ are the complex signals at axial time t_m corresponding to the jth A-scan and its respective conjugate; $\tilde{\Gamma}_{j+1}(t_m)$ and $\tilde{\Gamma}^*_{j+1}(t_m)$ are the complex signals at axial time t_m corresponding to the next A-scan and its respective conjugate; M is an even number that denotes the window size in the axial direction for each pixel; N is the number of sequential scans used to calculate the cross correlation; and T is the time duration between A-scans. Because T is much longer than the pixel time window within each scan used in the spectrogram method, high-velocity sensitivity can be achieved.

Phase-resolved ODT decouples spatial resolution and velocity sensitivity in flow images and increases imaging speed by more than two orders of magnitude, without compromising spatial resolution and velocity sensitivity. In addition, because two sequential A-line scans are compared at the same location, speckle modulations in the fringe signals cancel each other and, therefore, will not affect the phase difference calculation. Consequently, the phase-resolved method reduces the speckle noise in the velocity image. Furthermore, if the phase difference between sequential frames is used, the velocity sensitivity can be further increased. Real-time imaging with velocity sensitivity on the order of 10 μm/s has been demonstrated.

In addition to digital processing of the fringe signal using Hilbert transformation, the complex analytical signal can also be achieved through hardware implementation. Optical Hilbert transformation using polarization optics has been implemented for real-time phase-resolved ODT imaging. Real-time ODT imaging using hardware demodulation of the ODT signal has also been demonstrated.

Spectral Domain Phase-Resolved ODT Method

A schematic diagram of a spectral domain ODT system is shown in Figure 6. The signal from the Michelson interferometer is directly coupled to a

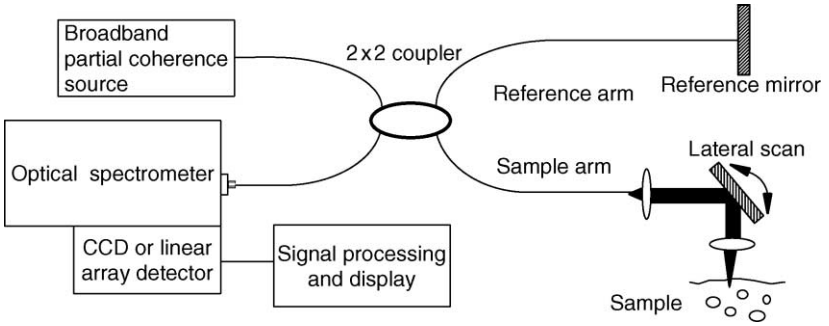

Figure 6 Schematic diagram of a spectral domain ODT instrument.

spectrometer that records the spectral fringe pattern, $P_{ODT}(\nu)$. The temporal interference fringe can be calculated by a Fourier transformation of the spectral fringe pattern (eqn [17]). The Doppler shift can then be determined from the phase shift between sequential scans using the phase-resolved ODT algorithm (eqns [23] and [24]).

Spectral domain phase-resolved ODT has the advantage that no optical delay line is required. In addition, the spectral domain method can achieve high signal to noise ratio over time domain ODT. Since parallel detection can be implemented with a high-speed spectrometer, high-speed imaging acquisition is possible. Finally, because the dynamic range of the phase-resolved ODT depends on the speed of the line scans, spectral domain ODT has the advantage in terms of imaging speed and velocity dynamic range.

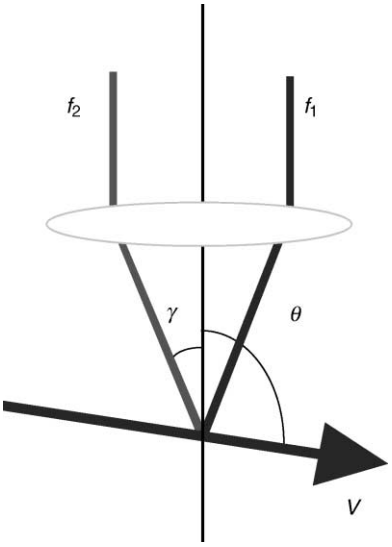

Figure 7 Effect of numerical aperture and transverse flow velocity on Doppler bandwidth.

Transverse Flow Velocity and Doppler Angle Determination

One of the limitations of using the Doppler shift to determine the flow is that the technique is only sensitive to longitudinal flow velocity (Figure 2). If one knows the flow direction, Doppler shift measurement can fully quantify the flow. However, in many biological cases, where flow direction is not known, Doppler shift measurement alone is not enough to fully quantify the flow. Furthermore, there are many clinical cases, such as ocular bloodflow, where vessels are in the plane perpendicular to the probing beam. When flow direction is perpendicular to the probing beam, the Doppler shift is not sensitive to transverse bloodflow (V_T). Therefore, a method to measure transverse flow velocity is essential.

Standard deviation of the Doppler spectra can be used to determine the transverse flow. The technique is based on the fact that ODT imaging uses a relatively large numeric aperture lens in the sampling arm. The beam from different sides of the edges will produce different Doppler shifts, f_1 and f_2, as indicated in Figure 7. Consequently, the Doppler spectra will be broadened by the transverse flow. If the incident beam has a Gaussian spectral profile and contributions from Brownian motion and other sources that are independent of the macroscopic flow velocity are included, a linear relation between standard deviation of the Doppler spectra and transverse flow velocity, $V_T = V \sin\theta$, can be derived:

$$\sigma = \frac{\pi V \sin\theta NA_{\text{eff}}}{8\lambda} + b \qquad [25]$$

where b is a constant, and NA_{eff} is the effective numeric aperture. The standard deviation can be determined from the measured analytical fringe

signal:

$$\sigma^2 = \frac{1}{2\pi^2 T^2} \times \left(1 - \frac{\left| \sum_{m=(n-1)M}^{nM} \sum_{j=1}^{N} \tilde{\Gamma}_j(t_m) \cdot \tilde{\Gamma}^*_{j+1}(t_m) \right|}{\frac{1}{2} \sum_{m=(n-1)M}^{nM} \sum_{j=1}^{N} [\tilde{\Gamma}_j(t_m) \cdot \tilde{\Gamma}^*_j(t_m) + \tilde{\Gamma}_{j+1}(t_m) \cdot \tilde{\Gamma}^*_{j+1}(t_m)]} \right) \quad [26]$$

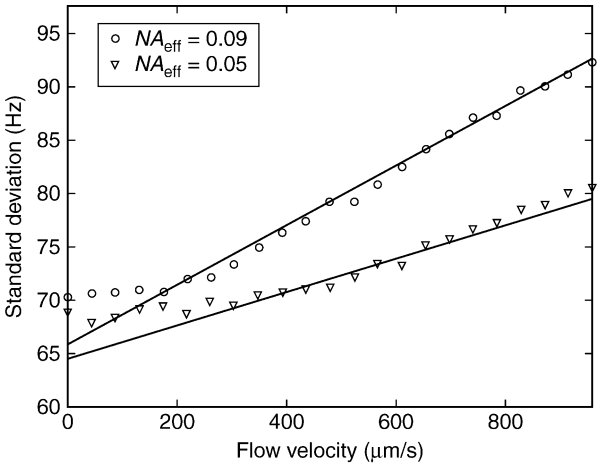

Figure 8 Standard deviation as a function of flow velocity for two different numeric apertures. Reproduced with permission from Ren *et al.* (2002) *Optics Letters* 27: 409–411.

The measured standard deviation as a function of transverse flow velocity is shown in Figure 8. As predicted, the Doppler bandwidth is a linear function of transverse flow velocity above a certain threshold level. The effective numerical aperture of the optical objective in the sample arm determines the slope of this dependence. This result indicates that standard deviation can be used to determine the transverse flow velocity. Since both longitudinal and transverse flow velocity (V_L and V_T) can be measured by the Doppler shift and standard deviation, respectively, flow direction can be determined from a single measurement of the Doppler fringe signal.

Applications

Due to its exceptionally high spatial resolution and velocity sensitivity, several clinical applications of ODT have been demonstrated, including screening vasoactive drugs, monitoring changes in image tissue morphology and hemodynamics following pharmacological intervention and photodynamic therapy, evaluating the efficacy of laser treatment in port wine stain (PWS) patients, assessing the depth of burn wounds, mapping cortical hemodynamics for brain research, imaging ocular bloodflow, and

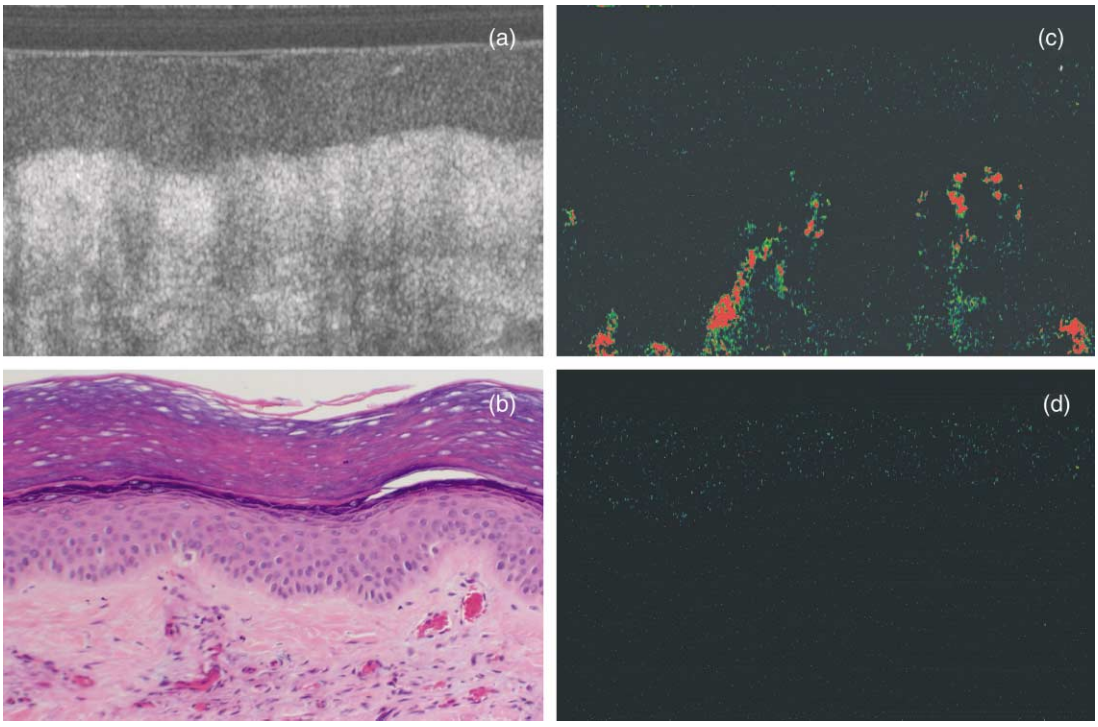

Figure 9 ODT images taken *in situ* from PWS human skin. (a) Structural image, (b) histological section, (c) image before laser treatment, and (d) image after laser treatment (scale bar 100 μm). Reproduced with permission from Nelson *et al.* (2001) *Archives of Dermatology* 137: 741–744. Copyright © 2001, American Medical Association. All rights reserved.

mapping bloodflow in gastrointestinal tracts. Figure 9 shows ODT structural and flow velocity images of a patient with PWS before and after laser treatment, respectively. For comparison, a histology picture taken at the same site is included. The vessel location from the ODT measurement and histology agree very well. Furthermore, the destruction of the vessel by laser can be identified, since no flow appears on the Doppler flow image after laser treatment.

Three-dimensional images of a microvascular network can be obtained by stacking 2D scans together. It is known that the microvasculature of mammary tumors has several distinct differences from normal tissues. Mapping of a 3D cancer microvascular network could provide additional information for cancer diagnosis. Figure 10 shows multiple blood vessels imaged from a patient with an abnormal microvascular network. Different colors represent different signs of the Doppler shift, which depends on the angle between the direction of flow and probing beam.

ODT is also a powerful tool to study flow dynamics in microfluidic channels. In addition to imaging flow velocity profile, ODT can also be used to measure osmotic mobility, quantify size of the scattering particle, and study flow dynamics of microfluids in microchannels of different materials, geometry, and surface treatment.

Polarization Sensitive OCT

PS-OCT combines polarization sensitive detection with OCT to determine tissue birefringence. PS-OCT can obtain enhanced image contrast and additional physiological information by studying polarization properties of biological tissues. Many biological tissues, such as tendon, muscle, nerve, bone, cartilage, and skin, exhibit birefringence properties. Consequently, PS-OCT can provide contrast mechanisms that are directly related to the physiological conditions of these tissues.

The polarization state of a light beam can be described by a Stokes vector **S** as:

$$\mathbf{S} = \begin{bmatrix} I \\ Q \\ U \\ V \end{bmatrix} = \begin{bmatrix} a_x^2 + a_y^2 \\ a_x^2 - a_y^2 \\ 2a_x a_y \cos\varphi \\ 2a_x a_y \sin\varphi \end{bmatrix} \quad [27]$$

where I, Q, U, V are Stokes parameters, a_x and a_y are amplitudes of two orthogonal components of the electric vector, and φ represents the phase difference between the two components.

The effect of an optical device on the polarization of light can be characterized by a 4×4 Mueller matrix. The matrix acts on the input state, $\mathbf{S}_1$, to give the output state, $\mathbf{S}_2$:

$$\mathbf{S}_2 = \begin{bmatrix} I_2 \\ Q_2 \\ U_2 \\ V_2 \end{bmatrix} = \mathbf{M}\mathbf{S}_1$$

$$= \begin{bmatrix} M_{00} & M_{01} & M_{02} & M_{03} \\ M_{10} & M_{11} & M_{12} & M_{13} \\ M_{20} & M_{21} & M_{22} & M_{23} \\ M_{30} & M_{31} & M_{32} & M_{33} \end{bmatrix} \begin{bmatrix} I_1 \\ Q_1 \\ U_1 \\ V_1 \end{bmatrix} \quad [28]$$

In the Poincaré sphere representation, a polarization state, **S**, can be represented by a point (Q, U, V). The Poincaré sphere representation provides a convenient method to evaluate changes of Stokes vectors. Determination of either the Stokes vector or the Mueller matrix allows full quantification of birefringence properties of the biological sample.

A fiber-based, high-speed PS-OCT system is shown in Figure 11. The system is similar to the ODT system, except a polarization modulator and two orthogonal detection channels are included. Due to the coherence detection intrinsic to OCT, backscattered light that

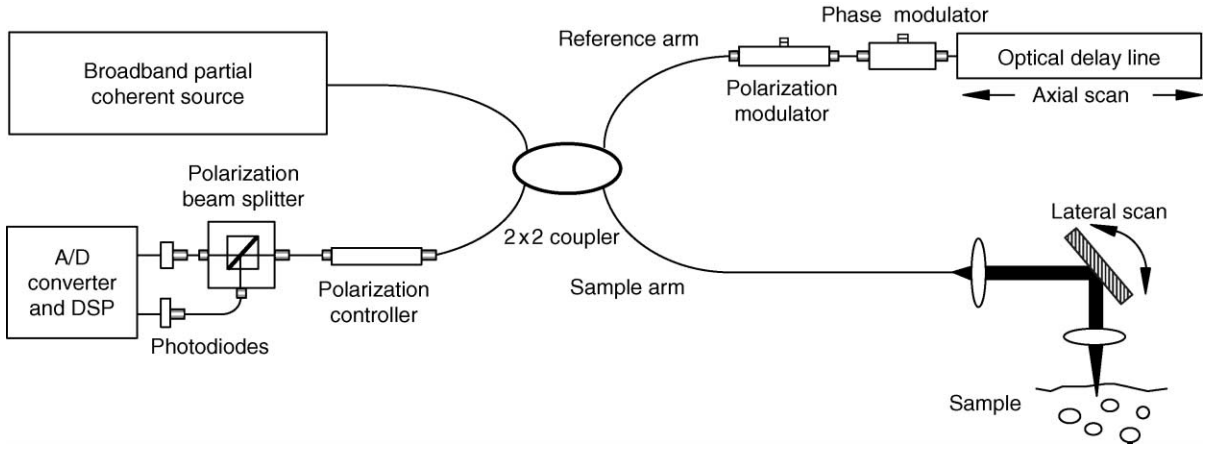

Figure 11 Fiber-based PS-OCT system. DSP: digital signal processing.

originates from incident light in different polarization states can be determined by controlling polarization states in the reference arm. Modulating the reference light in four orthogonal polarization states allows coherent detection of backscattered light from the sample under equivalent illumination in four different polarization states. The choice of orthogonal polarization states in the Poincaré sphere is important because it ensures that the birefringence measurements will be independent of the orientation of the optical axis in the sample.

For every polarization state controlled by the polarization modulator, the A-scan signals corresponding to the two orthogonal polarization diversity channels are digitized. The coherence matrix can be calculated from the complex electrical field vector from these two channels:

$$J = \begin{bmatrix} \langle E_{\mathrm{H}}^{*}(t)E_{\mathrm{H}}(t)\rangle & \langle E_{\mathrm{H}}^{*}(t)E_{\mathrm{V}}(t)\rangle \\ \langle E_{\mathrm{V}}^{*}(t)E_{\mathrm{H}}(t)\rangle & \langle E_{\mathrm{V}}^{*}(t)E_{\mathrm{V}}(t)\rangle \end{bmatrix} = \begin{bmatrix} J_{\mathrm{HH}} & J_{\mathrm{HV}} \\ J_{\mathrm{VH}} & J_{\mathrm{VV}} \end{bmatrix} \quad [29]$$

where E_{H}, E_{V} are the components of the complex electric field vector corresponding to horizontal and vertical polarization channels, respectively, and E_{H}^{*}, E_{V}^{*} are their conjugates, respectively. The Stokes vector can be derived from the coherence matrix:

$$\begin{aligned} S_0 &= J_{\mathrm{HH}} + J_{\mathrm{VV}} & S_2 &= S_0^{-1}(J_{\mathrm{HV}} + J_{\mathrm{VH}}) \\ S_1 &= S_0^{-1}(J_{\mathrm{HH}} - J_{\mathrm{VV}}) & S_3 &= iS_0^{-1}(J_{\mathrm{VH}} - J_{\mathrm{HV}}) \end{aligned} \quad [30]$$

where S_1, S_2, and S_3 are the normalized coordinates of the Stokes vector in the Poincaré sphere, characterizing the polarization state of the backscattered light, and S_0 is the module of the Stokes vector characterizing light intensity. The Stokes vector, corresponding to each of the input polarization states for the nth pixel in the jth A-scan, can be calculated as:

$$\begin{aligned} S_{0,n} &= \sum_{m=(n-1)M}^{nM} \left[\tilde{\Gamma}_j^{\mathrm{H}}(t_m)\tilde{\Gamma}_j^{\mathrm{H}^*}(t_m) + \tilde{\Gamma}_j^{\mathrm{V}}(t_m)\tilde{\Gamma}_j^{\mathrm{V}^*}(t_m)\right] \\ S_{1,n} &= S_{0,n}^{-1} \sum_{m=(n-1)M}^{nM} \left[\tilde{\Gamma}_j^{\mathrm{H}}(t_m)\tilde{\Gamma}_j^{\mathrm{H}^*}(t_m) - \tilde{\Gamma}_j^{\mathrm{V}}(t_m)\tilde{\Gamma}_j^{\mathrm{V}^*}(t_m)\right] \\ S_{2,n} &= S_{0,n}^{-1} \sum_{m=(n-1)M}^{nM} 2\,\mathrm{Re}\left(\tilde{\Gamma}_j^{\mathrm{H}^*}(t_m)\tilde{\Gamma}_j^{\mathrm{V}}(t_m)\right) \\ S_{3,n} &= S_{0,n}^{-1} \sum_{m=(n-1)M}^{nM} 2\,\mathrm{Im}\left(\tilde{\Gamma}_j^{\mathrm{H}^*}(t_m)\tilde{\Gamma}_j^{\mathrm{V}}(t_m)\right) \end{aligned} \quad [31]$$

where M is an integer number that determines the size of the average in the axial direction for each pixel; $\tilde{\Gamma}_j^{\mathrm{H}}(t_m)$ and $\tilde{\Gamma}_j^{\mathrm{V}}(t_m)$ are complex signals detected from the two orthogonal polarization channels at axial time t_m, for the jth A-scan; and $\tilde{\Gamma}_j^{\mathrm{H}^*}(t_m)$ and $\tilde{\Gamma}_j^{\mathrm{V}^*}(t_m)$ are their conjugates, respectively.

In order to measure the birefringence properties of the sample accurately, four states of light polarization are generated for each lateral pixel. For each polarization state, one A-line scan is performed. Therefore, a total of four A-line scans are used to calculate the Stokes vector and phase retardation images simultaneously.

For a sample with an assumed linear birefringence, there exists two eigenwaves that are polarized along the projected fast and slow axes of the sample normal to the propagation direction of incident light. The Stokes vectors of these eigenwaves determine a rotation axis in the equator plane of a Poincaré sphere.

The effect of birefringence is to rotate the Stokes vector about this axis through an angle that is equal to the phase retardation of the sample. Conversely, the rotation axis can be determined from the known polarization states of incident and backscattered light at the sample location. The phase retardation image, which characterizes the accumulated birefringence distribution in the sample, is calculated by the rotation of the Stokes vectors in the Poincaré sphere.

The simultaneous Stokes vectors and phase retardation images of a rat muscle are shown in Figure 12.

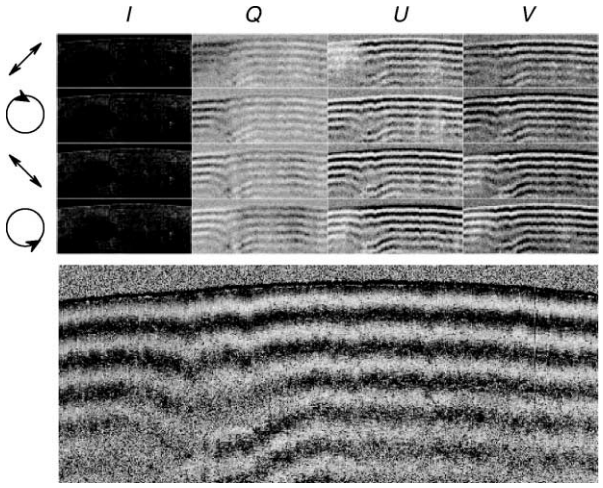

Figure 12 Stokes vectors images (top) and phase retardation image (bottom) in fresh rat muscle. The image area is 2 mm × 5 mm. Reproduced with permission from Ren *et al.* (2003) *SPIE Proceedings* 4956: 320–327.

Stokes vectors, corresponding to four different polarization states, are shown in the top figure. From Stokes vector images, the phase retardation image can be calculated as shown in the bottom figure. The banded structure in the phase retardation image indicates the accumulated tissue birefringence distribution in the rat muscle. In addition, differential optical axis and birefringence images can also be calculated.

There are a number of clinical applications for PS-OCT, including burn depth determination and retinal fiber nerve layer thickness evaluation. Figure 13 shows *in vivo* structural and phase retardation images from rat skin burned at 100°C for 10 seconds. Although the structure image shows very little contrast, the phase retardation image clearly shows the contrast between the normal and burned regions. As light propagates into the tissue, the retardation increases due to tissue birefringence. For normal tissue, it only takes less than 20 μm to cause a phase retardation of 90°. However, for the burned tissue, it takes much thicker tissue to cause the same phase retardation. The decrease of birefringence in thermally damaged tissue can clearly be seen in PS-OCT scans in comparison to normal rat skin.

Second Harmonic OCT

SH-OCT combines SHG with coherence gating for high-resolution tomographic imaging of tissue structures with molecular contrast. SHG is the lowest-order nonlinear optical process where the second-order nonlinear optical susceptibility is

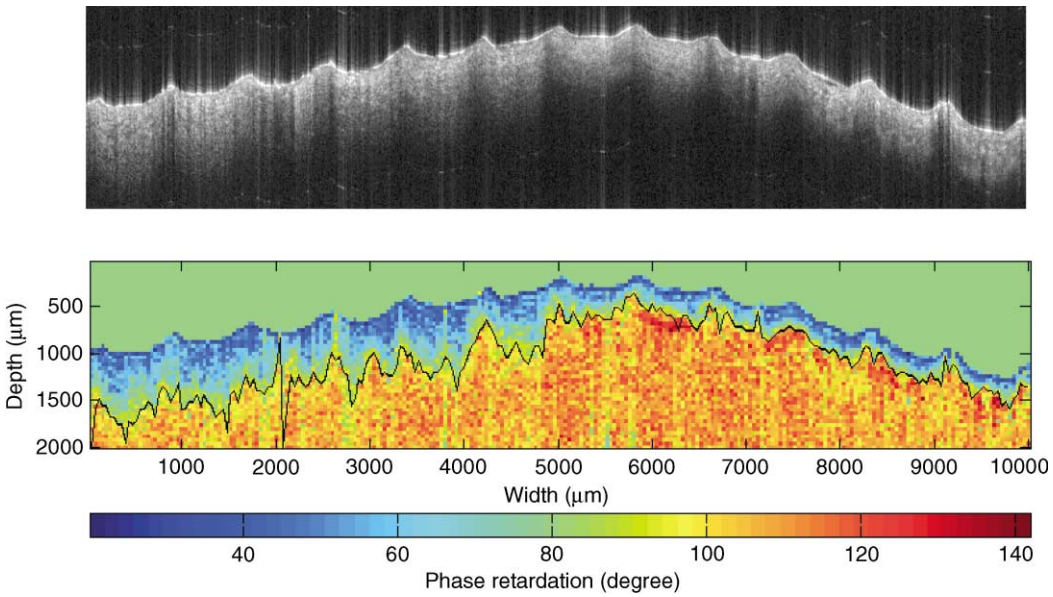

Figure 13 *In vivo* structure (top) and phase retardation image (bottom) from rat skin burned at 100°C for 10 seconds. The black contour line in the phase retardation image demarcates the depth at which 90° phase retardation has been reached with respect to the incident polarization (image size 2 mm × 10 mm).

responsible for the generation of light at second-harmonic frequency. Because second-order nonlinear optical susceptibility is very sensitive to electronic configurations, molecular structure and symmetry, local morphology, and ultrastructures, SHG provides molecular contrast for the coherence image.

The schematic diagram for SH-OCT is shown in Figure 14. A broadband short pulse laser is used as a light source in a Michelson interferometer. The light is split into the reference arm and the sample arm. In the reference arm, a thin nonlinear crystal is used to convert the input radiation to SH photons. Both SH and fundamental waves are then reflected by a metal mirror (M1) mounted on a motorized translation stage, which acts as the delay line in this SH-OCT system. A backscattered SH wave from the sample recombines with the SH wave from the reference arms to form interference fringe. The SH interference fringe signal is detected by a photomultiplier tube (PMT) after passing through a short-pass filter (F1). The fundamental interference fringe signal is detected by a photodiode (PD) after passing through a long-pass filter (F2).

A SH-OCT image of a rat tendon is shown in Figure 15. Compared with conventional OCT performed at fundamental wavelengths, SH-OCT offers enhanced molecular contrast and spatial resolution. It is also an improvement over existing SHG scanning microscopy technology as the intrinsic coherence gating mechanism enables the detection and discrimination of SH signals generated at deeper locations. The enhanced molecular contrast of SH-OCT extends conventional OCT's capability for detecting small changes in molecular structure. SH-OCT is promising for the diagnosis of cancers and other diseases at an early stage when changes in tissue and molecular structure are small.

Conclusions

Optical tomography is a rapidly developing imaging technology with many potential applications. Through different contrast enhancement mechanisms, ODT, PS-OCT, and SH-OCT provide clinically important physiological information that is not available in the structure image. Given the noninvasive nature and exceptionally high spatial resolution, optical tomography can simultaneously provide tissue structure, blood perfusion, birefringence, and other physiological information and have great potential for basic biomedical research and clinical medicine.

Acknowledgments

I would like to thank many of my colleagues who have contributed to the functional OCT project at the Beckman Laser Institute and Center for Biomedical Engineering at UCI, particularly the students and postdoctoral fellows. I also want to acknowledge the research grants awarded from the National Institutes of Health (EB-00293, NCI-91717, RR-01192 and EB-00255), the National Science Foundation (BES-86924), the Whitaker

Foundation (WF-23281) and the Defense Advanced Research Program Agency (Bioflip program). Institutional support from the Air Force Office of Scientific Research (F49620-00-1-0371), and the Beckman Laser Institute Endowment are also gratefully acknowledged. Dr Chen's e-mail address is zchen@bli.uci.edu.

List of Units and Nomenclature

OCT	Optical coherence tomography
ODT	Optical Doppler tomography
PS-OCT	Polarization sensitive OCT
SH-OCT	Second harmonic OCT
STFFT	Short time fast Fourier transformation

Generation of Femtosecond Pulses

D T Reid, Heriot-Watt University, Edinburgh, UK

Introduction

Optical pulses from femtosecond lasers represent some of the shortest physical events ever observed and their high instantaneous powers allow them to be focused to intensities that can heat and compress matter to resemble the extreme conditions found in a nuclear explosion. The extreme units of time and power needed to describe this area of physics can easily distract from the simple and elegant techniques by which femtosecond pulses can be generated. The review presented here is divided into two main sections. The first explains the theory of pulse generation and shaping and the second concentrates on actual femtosecond laser sources in common use today.

Theory of Femtosecond Pulse Generation

Active Mode-locking

In an inhomogeneously broadened laser system, optical frequencies within the emission bandwidth of the material can experience gain simultaneously at discrete frequencies corresponding to the longitudinal modes of the laser resonator. In the absence of any mechanism to coherently couple energy between these modes, the laser will operate with a continuous-wave (cw) output containing a narrow band of frequencies whose roundtrip cavity gain is highest. An alternative operating regime exists in which each mode is related to its neighbor by a fixed phase relationship and it is this mode-locked condition that is used to generate a periodic sequence of ultrashort optical pulses.

To understand how mode-locking works, consider the frequency separation between adjacent longitudinal resonator modes which can be expressed as

$$\Delta\omega = 2\pi c/l \qquad [1]$$

where l is the optical roundtrip length of the resonator and c is the speed of light. If the nth longitudinal mode has an amplitude E_n then the total optical field can be denoted in complex notation as

$$E(t) = \sum_n E_n \exp \mathrm{i}[(\omega_0 + n\Delta\omega)t + n\Delta\varphi] \qquad [2]$$

with ω_0 being the center frequency of the output and $\Delta\varphi$ being the phase difference between adjacent modes. Figure 1 illustrates how a simple pulse can be produced by coherently adding together adjacent modes. In Figure 1a, three modes with equal amplitudes and the same initial phase ($\Delta\varphi = 0$) are interfered to give a pulse. As further modes are added (Figure 1b) the pulse duration decreases.

Coupling of energy between adjacent cavity modes can be achieved in practice by modulating either the

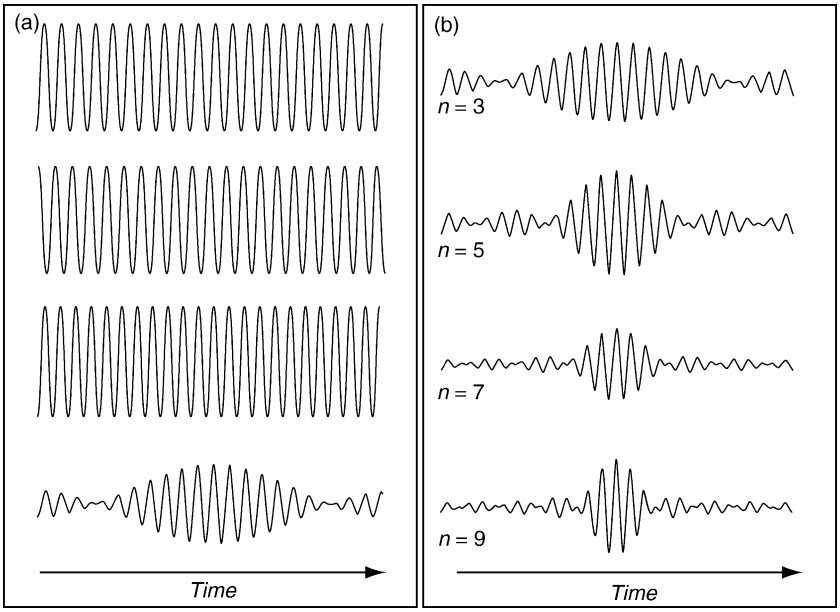

Figure 1 The principles of mode-locking: (a) three adjacent modes add coherently to produce a pulse; (b) shorter pulses require a larger number of *n* coupled modes.

intracavity loss (amplitude modulation (AM) mode-locking) or the intracavity phase (frequency modulation (FM) mode-locking). A common practical amplitude modulator is an acousto-optic modulator and for operation in the visible and near-infrared, fused silica is a common acousto-optic modulator material. Lithium-niobate devices based on the Pockels effect are the most commonly used phase modulators and are attractive for mode-locked fiber-laser applications because fiber-pigtailed waveguide devices are readily available.

Active mode-locking has been employed in a wide variety of laser systems including argon ion, dye, erbium-doped fiber, semiconductor, and solid-state lasers. Unlike passive mode-locking, no optical nonlinearity is required which means that actively mode-locked lasers can be operated with low intracavity powers. The technique is particularly suitable for mode-locked sources which require active synchronization to an external clock source.

A form of 'optical' active mode-locking exists in which gain modulation resulting from optical pumping using another mode-locked laser is the mode-locking mechanism. Known as synchronously pumped mode-locking, this technique has been used to obtain ultrashort pulses from oscillators incorporating gain media of laser or nonlinear optical materials. The technique is most appropriate to laser gain materials which have a short-lived fluorescence lifetime and whose gain therefore exhibits a significant change when the pump light is modulated at high frequencies. Synchronous pumping has been used to generate mode-locked pulses from color-center lasers, dye lasers, and optical parametric oscillators.

Passive Mode-locking

To produce the shortest optical pulses, passive mode-locking, a technique based on exploiting intracavity optical nonlinearities, must be employed. Unlike the active technique, the strength of the mode-locking action increases as the propagating pulses shorten and their peak intensities rise. One consequence of this nonlinear behavior is that the passive technique commonly generates and mode-locks entirely new cavity frequencies which were not originally present during cw operation.

Passive mode-locking has been implemented using a wide range of different nonlinear effects, but in every technique the mode-locking process can be described in terms of dynamic loss saturation combined, in certain systems, with dynamic gain saturation. The principal mode-locking element is a saturable absorber whose loss decreases as the incident pulse intensity increases. A saturable absorber can take the form either of a resonant component such as a solid-state semiconductor device or a dye jet with a fixed absorption wavelength, or a nonresonant component that replicates a saturable-absorber-like action using self-focusing or self-phase-modulation effects. Saturable absorbers can be categorized as either slow saturable absorbers or fast saturable

absorbers, depending on whether their recovery time is longer or shorter than the pulse duration, respectively. The pulse-shaping mechanisms are different in each case and will be described separately.

Slow saturable absorbers are physical devices, commonly dye molecules in solution or semiconductor-doped glass, which rely on resonant excitation to produce an excited electronic state whose transmission is greater than that of the ground state. When an optical pulse is incident on a slow absorber, its leading edge is absorbed and creates an excited state which is relatively transparent to the trailing edge. In a laser medium whose gain is readily saturated, a pulse propagating first through the absorber and then through the gain medium experiences a 'gain window' with a finite duration which strongly shapes the pulse (see Figure 2a,b).

A fast saturable absorber is required to realize mode-locking in laser media which are not easily saturated. The time-dependent gain and loss profiles of the absorber and the gain medium are again depicted in Figure 2c,d and refer to an absorber with both a rapid response and recovery time. In this system, the dynamics of the absorber and gain medium no longer represent the limiting factor influencing the pulse duration, and other effects such as linear and nonlinear dispersion become the dominant pulse-shaping mechanisms.

Pulse Shaping by Material Dispersion

Intense pulses propagating in a mode-locked laser experience strong linear and nonlinear shaping effects associated, respectively, with group-velocity dispersion and self-phase-modulation. Contributions to the net intracavity dispersion arise from the gain medium, the cavity mirrors, other elements such as intracavity prisms, even the air in the beam path. Dispersive effects in materials originate as a result of a frequency-dependent dielectric susceptibility:

$$P(\omega) = \varepsilon_0 \chi^{(1)}(\omega) E(\omega) + \varepsilon_0 \chi^{(2)}(\omega) E(\omega)^2 + \varepsilon_0 \chi^{(3)}(\omega) E(\omega)^3 + \cdots \quad [3]$$

which is due to physical resonances (poles) in the electronic response to an applied E-field.

Linear dispersion

Linear dispersion refers to the variation of the refractive index associated with the real part of the $\chi^{(1)}$ term, namely,

$$n_0 = \sqrt{1 + \mathrm{Re}\{\chi^{(1)}\}} \quad [4]$$

and leads to a wavelength-dependent group velocity which is responsible for pulse broadening and break-up in optical systems. Dispersive effects are best analyzed in terms of optical phase which is related to the refractive index by

$$\varphi(\omega) = \frac{n_0(\omega)\omega L}{c} \quad [5]$$

where L is the medium length and c is the vacuum speed of light. The local variation of the spectral

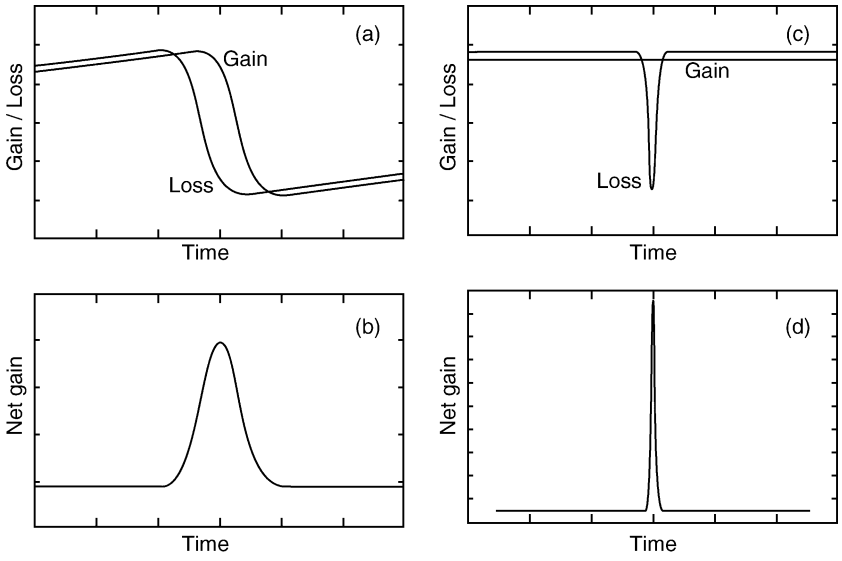

Figure 2 Saturable absorber action: (a) intracavity gain and loss profiles for a laser comprising a slow saturable absorber and a rapid relaxation time gain medium, and (b) the net gain (gain − loss) for this system; (c) gain and loss profiles for a laser comprising a near-instantaneous saturable absorber and a slow relaxation time gain medium, and (d) the net gain for this system.

phase due to an optical medium can be represented as the Taylor series

$$\varphi(\omega) = \varphi(\omega_0) + (\omega - \omega_0)\frac{d\varphi}{d\omega}\bigg|_{\omega_0} + \frac{1}{2}(\omega - \omega_0)^2 \frac{d^2\varphi}{d\omega^2}\bigg|_{\omega_0} + \left|\frac{1}{6}(\omega - \omega_0)^3 \frac{d^3\varphi}{d\omega^3}\right|_{\omega_0} + \cdots \quad [6]$$

where ω_0 is the center frequency of the incident light. When an ultrashort pulse propagates through the medium, only the quadratic and higher-order terms in [6] have a direct influence on the shape of the pulse in time. The $(\omega - \omega_0)^2$ term is responsible for adding linear chirp which refers to a time-varying linear increase or decrease in the instantaneous optical frequency across the pulse. Obtaining the shortest pulses from a mode-locked laser requires the quadratic and higher-order terms in the roundtrip intracavity spectral phase to be zero. In practice this means minimizing the material group-velocity dispersion of the gain medium by using a short but highly doped laser crystal and then identifying additional optical elements whose group-velocity dispersion is equal in magnitude but opposite in sign to that of the crystal. Optical components for compensating group-velocity dispersion fall into two categories: those which use bulk optics and geometry to achieve a wavelength-dependent path length, and others based on interference effects within a dielectric optical coating.

Geometrical methods of dispersion compensation are commonly based on pairs of diffraction gratings or prisms and in both cases the geometry of the systems means that the group delay is wavelength dependent and can be made greater for longer wavelengths than for shorter ones. Analytic expressions describing the quadratic and cubic spectral phase of prism and diffraction grating pairs are summarized in Table 1. Dispersion compensation using prisms has been extremely successful and 11-fs pulses were reported using this approach. The simultaneous compensation of arbitrary second- and third-order spectral phase is, however, difficult and involves identifying a suitable prism material, apex spacing, and tip insertion. The expressions listed in Table 1 indicate that the form of the spectral phase depends on the refractive index of the prism material and its wavelength derivatives, while the apex separation, l, also contributes to a large extent. A further contribution to the spectral phase comes from the glass encountered by the beam passing through the prism tips which contributes a positive dispersion described by the equations for a bulk material given in Table 1. In general, an iterative solution of the equations given in Table 1 is needed to determine the geometry of a prism pair suitable for producing a desired spectral phase profile.

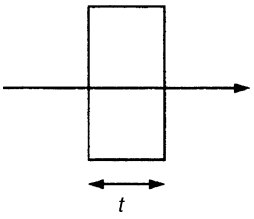
Laser cavity mirrors can be designed with chirped multilayer dielectric coatings which possess a chosen group-velocity dispersion profile. A Bragg mirror with smaller layer periods at the surface and larger periods deeper in the coating provides negative group-velocity dispersion because the longer wavelengths experience larger group delays within the coating than the shorter ones. These chirped mirrors provide constant reflectivity across their stopband and therefore only modify the spectral phase of a pulse, leaving the intensity unchanged. The design of chirped mirrors has been refined in recent years to enhance their operating bandwidth and to reduce undesirable modulations in the group-delay response. The technique has been used to obtain 6.5-fs pulses directly from a Ti:sapphire oscillator and to achieve compression of amplified pulses to below 5 fs.

Nonlinear dispersion

Nonlinear effects arise in all materials due to the $\chi^{(3)}$ term in [3]. In a transparent medium the refractive index due to this net susceptibility is approximately

$$n \approx n_0 + \frac{\chi^{(3)}E^2}{2n_0} = n_0 + n_2 I \quad [7]$$

where I is the optical intensity. The importance of the $\chi^{(3)}$ susceptibility is therefore that it causes the refractive index to become intensity-dependent, and significant changes in the refractive index can be induced by the high peak intensities of ultrashort pulses.



Self-phase-modulation (SPM) resulting from the nonlinear refractive index is essential in generating the shortest pulses from modern ultrafast lasers and is caused by the time-varying intensity profile of the pulse. The higher-intensity components induce a larger nonlinear refractive index change and therefore experience a greater phase shift than the weaker components. The resulting frequency shift across the pulse can be shown to be

$$\Omega(t) = -\frac{d\phi(t)}{dt} = -\frac{\omega n_2 L}{c}\frac{dI(t)}{dt} \quad [8]$$

which describes a redshift of the pulse leading edge and a blueshift of the trailing edge. Only the pulse center frequency remains unchanged and SPM therefore broadens the pulse spectrum by redistributing energy from the center to the wings. Across the center of the pulse, SPM leads to an approximately linear positive chirp that, with appropriate optics, can be

$$\frac{d^3\varphi}{d\omega^3} = -6l\frac{\lambda^4}{c^3d^2}\left(1 + \frac{\lambda}{d}\sin\gamma - \sin^2\gamma\right)\left[1 - \left(\frac{\lambda}{d} - \sin\gamma\right)^2\right]^{-5/2}$$

corrected using an equal but opposite amount of negative second-order dispersion. The combination of spectral broadening using SPM and subsequent chirp-removal using linear dispersion is the basis for optical pulse compression techniques that have been applied effectively to create pulses which exist for only a few carrier-wave periods.

When the pulse propagates in an environment where SPM and linear dispersion are well balanced and evenly distributed, a soliton will evolve which, in the absence of loss, can propagate indefinitely without changing shape. The nonlinear Schrödinger equation predicts that lasers in which the dominant pulse-shaping mechanisms are negative

group-velocity dispersion and self-phase-modulation will produce soliton-like pulses with a $\mathrm{sech}^2(t)$ intensity profile. In experimental measurements of ultrafast lasers the pulse shape is commonly assumed to be $\mathrm{sech}^2(t)$ and the chirp of the pulses is then estimated by measuring their duration–bandwidth product, $\Delta\nu\Delta\tau$, which is a dimensionless quantity that can be treated as a figure-of-merit for ultrashort pulses. For unchirped pulses the duration–bandwidth product is independent of their duration or spectral bandwidth but is sensitive to their shape: chirp-free Gaussian pulses have $\Delta\nu\Delta\tau = 0.441$ while $\mathrm{sech}^2(t)$ pulses have $\Delta\nu\Delta\tau = 0.315$.

Sources of Femtosecond Pulses

Dye Lasers

The first practical passively mode-locked ultrafast lasers were those based on a gain medium of a thin ($\sim$10 μm) organic dye jet and incorporating a slow saturable absorber jet at a separate cavity focus. The most common combination was Rhodamine 6G in ethylene glycol (gain jet) and 3,3-diethyloxadicarbocyanine iodide in ethylene glycol (absorber jet) which produced pulses at a wavelength of 620 nm. The most successful approach was colliding-pulse mode-locking in which two counter-propagating pulses within a ring cavity are synchronized to arrive simultaneously at the absorber jet, so achieving greater saturation of the absorber and allowing the pulses to be transmitted with a loss significantly smaller than in the single-pulse case. The first sub-100-fs optical pulses were reported in 1981 from a colliding-pulse mode-locking dye laser and later work reported pulse durations as low as 27 fs but the configuration was inefficient and produced low average output powers. Other approaches such as synchronous pumping and hybrid mode-locking produced higher output powers but the maintenance-intensive nature of dye lasers and the hazardous nature of many of the chemicals used led to their gradual replacement by more convenient solid-state alternatives, based principally on Ti:sapphire.

Color-Center Lasers

A new source of femtosecond pulses in the near-infrared was reported in 1984. Coined the soliton laser the system was a synchronously pumped KCl:Tl color-center laser tunable from 1.4 to 1.6 μm and modified to allow direct generation of pulses as short as 50 fs, substantially shorter than the 8 ps achieved in synchronously pumped operation alone. Femtosecond operation was achieved by coupling a length of polarization-preserving anomalously dispersive fiber to the main laser cavity using a beamsplitter and retroreflector arrangement. This coupled-cavity arrangement later became known as additive pulse mode-locking (APM) and produced short pulses when the optical length of the fiber was adjusted to be an integral multiple of the main cavity length. The long upper-state lifetime of the laser-active centers in the KCl:Tl gain medium allowed particularly stable APM operation, but mode-locking of this kind was also successfully employed in an actively stabilized $NaCl:OH^-$ color-center laser to produce 110-fs pulses. The need to maintain color-center crystals at liquid-nitrogen temperatures limited the convenience of these lasers but until the advent of Ti:sapphire they remained the only solid-state sources capable of femtosecond operation.

Ti:sapphire Lasers

The creation in 1986 of a new broadband laser material – titanium-doped sapphire or Ti:sapphire – began a revolution in ultrafast laser sources that still continues today. Unlike other contemporary solid-state materials for mode-locked lasers such as Nd:YAG, Ti:sapphire is a vibronic gain medium which exhibits a strong electron-phonon coupling between the titanium ion transition and the host lattice. This vibronic coupling leads to a broad continuum of possible transition energies and results in a fluorescence bandwidth covering 670–1050 nm, making Ti:sapphire capable of supporting extremely short femtosecond pulses. The long fluorescence lifetime of Ti:sapphire means that, unlike dye lasers, femtosecond mode-locking requires a passive method using a fast saturable absorber and two methods have prevailed and are discussed below.

The first passively mode-locked Ti:sapphire lasers were based on the APM technique in which mode-locking is achieved by a fast-saturable absorber action due to interference between the intracavity pulse and a self-phase-modulated replica propagating in an auxiliary cavity. An important breakthrough was made in 1990 when it was reported that an APM Ti:sapphire laser continued to operate even when the auxiliary cavity was blocked. This discovery was attributed to an entirely new mode-locking effect known as Kerr-lens mode-locking (KLM) or self-mode-locking in which the presence of a Kerr lens within the gain medium during mode-locked operation changes the mode focusing within the cavity so that, compared to cw operation, mode-locked pulses experience higher gain. Two configurations of KLM exist and are known as soft aperture mode-locking, where the presence of the Kerr lens increases the gain by improving the overlap between the pump and laser

modes, and hard-aperture mode-locking, in which a physical aperture such as a slit or the edge of a prism is adjusted to introduce greater loss for cw operation. Because KLM is based on a nonresonant nonlinearity, Ti:sapphire lasers can be mode-locked at any wavelength in their gain bandwidth using this technique. Recent advances in controlling the intracavity group-velocity dispersion characteristics have led to the generation of sub-5-fs pulses directly from a Ti:sapphire oscillator. The principal drawback of the KLM method is that it is not self-starting because mode-locked operation must be seeded by an intense noise spike or other short fluctuation. Different starting methods have been applied successfully including mirror tapping, acousto-optic modulation, and mode-dragging, and once mode-locking has been initiated it is generally stable until some external perturbation disturbs the intracavity beam.

An alternative method for obtaining femtosecond pulses has been pioneered largely in parallel with the KLM efforts and is based on using resonant nonlinearities in semiconductors as fast saturable absorbers. The approach is to fabricate a semiconductor multiple-quantum-well (MQW) device whose bandgap has been chosen to match the laser wavelength and whose absorption can be saturated at high fluences. Initially these devices were utilized in an APM geometry in which the MQW device was situated in an auxiliary cavity but it was later realized that an equivalent monolithic configuration could be obtained by sandwiching the MQW layer between two high-reflectivity mirrors (see Figure 3, inset) to form a Fabry–Perot structure and the resulting element was known as an antiresonant Fabry–Perot saturable absorber. The first application of a such a semiconductor saturable absorber mirror (SESAM) for mode-locking Ti:sapphire was reported in 1995 where self-starting operation was demonstrated. A typical modern Ti:sapphire laser design is shown in Figure 3 and illustrates how a saturable absorber mirror can be integrated into the cavity. Further design enhancements such as reducing the finesse of the Fabry–Perot cavity resulted in SESAMs with a broader wavelength response which enabled sub-10-fs self-starting operation.

Fiber Lasers

Ultrafast fiber lasers, particularly those based on silica doped with rare earth Er^{3+}, Nd^{3+}, or Yb^{3+}ions, have enjoyed renewed attention in recent years as efforts to scale their average output powers and pulse energies to practical levels have proved successful. Four main mode-locking strategies have been applied to these systems: active mode-locking which is generally restricted to picosecond generation; intensity-dependent feedback using a nonlinear amplifying loop mirror; polarization APM; and semiconductor saturable absorber mode-locking. The upper-state lifetime of rare-earth-doped fibers is long and therefore a fast saturable absorber mechanism is necessary for passive mode-locking, limiting the choice of mode-locking elements to those based on Kerr or semiconductor nonlinearities.

The development of mode-locked fiber sources has concentrated on Er-doped lasers because of the compatibility of their output wavelengths with the 1.5 μm optical communication window in standard silica fiber. Passively mode-locked designs based on the nonlinear loop mirror work by exploiting the Kerr effect in an intracavity fiber Sagnac interferometer containing a gain section. With suitable control of the intracavity polarization, such a nonlinear amplifying loop mirror (NALM) can be set up to transmit light of high intensities but reflect low intensities because of the differential phase shift induced between the two interferometer arms. By adding the loop mirror to a unidirectional ring cavity a figure-of-eight laser is formed (Figure 4) which is capable of producing femtosecond soliton pulses with average powers of around 1 mW. Drawbacks of the figure-of-eight laser include the presence of spectral sidebands at the shortest pulse durations and a tendency for multiple pulse operation. Mode-locking can also be achieved

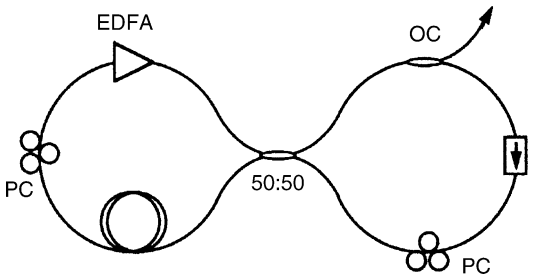

Figure 4 Schematic of a figure-of-eight femtosecond fiber laser. EDFA, erbium-doped fiber amplifier gain section; OC, output coupler; PC, polarization controller.

using a variation on the APM technique and significant average output powers have been demonstrated from stretched-pulse-APM lasers, with up to 90 mW being reported at pulse energies of 2.25 nJ.

Semiconductor saturable absorber mode-locking has been demonstrated in fiber lasers using a variety of configurations including bulk InGaAsP on InP and saturable Bragg reflectors based on InGaAs/InP MQWs on a AlAs/GaAs mirror structure. Fiber lasers mode-locked using semiconductor saturable absorbers are self-starting and exhibit stable mode-locking, normally at the fundamental cavity frequency. The narrow bandwidth of saturable absorber devices at near-infrared wavelengths makes the generation of sub-100-fs pulses difficult.

Semiconductor Sources

Diode lasers and external-cavity lasers based on semiconductor optical amplifiers (SOAs) are of importance because of their ability to produce ultrashort pulses from a compact system at wavelengths of relevance to optical fiber communications. The two principal methods used to generate ultrashort pulses from such devices are mode-locking with an external cavity or gain-switching (equivalently known as Q-switching) in a bow-tie waveguide structure. Subpicosecond pulse durations are now routinely produced using dispersion compensation and/or nonlinear pulse compression techniques and, by combining these strategies with Er:fiber amplification, 20-fs pulses have been produced. The mode-locking and gain-switching techniques each have their individual advantages. Gain-switching provides a simple and compact approach offering high average output power, but significant timing jitter and poor spectral quality can accompany pulses produced in this way. Mode-locked systems are physically larger than gain-switched devices because they require an external cavity and additional optical components, but shorter and higher quality pulses are achievable.

Other Common Solid-State Laser Sources

Certain solid-state gain media offer the potential for direct diode pumping, miniaturization and operation at wavelengths or average powers not accessible with other sources. Systems based on Nd or Cr ion transitions have been shown to be capable of ultrashort picosecond or femtosecond operation. Femtosecond mode-locking (175 fs) has been reported in Nd:glass which has one of the broadest fluorescence spectra of the Nd materials. Crystals with active ions of Cr^{2+}, Cr^{3+}, and Cr^{4+} have broad transitions covering wavelengths in the 2.0 μm, 800 nm and 1.4 μm regions and femtosecond operation has been demonstrated in Cr^{4+}:YAG at 1.52 μm, Cr^{4+}:Mg_2SiO_4 (Cr:forsterite) at 1.25 μm, Cr^{3+}:$LiSrAlF_4$ (Cr:LiSAF) at 850 nm, and Cr^{3+}:$LiSrGaF_6$ (Cr:LiSGAF). Direct diode pumping of Cr-ion-based lasers is attractive because of the opportunities for producing low-noise, compact, and efficient femtosecond sources, but the limited power available from high-quality pump diodes results in low intracavity powers which make KLM operation difficult. As a result, stable operation is better achieved using a physical saturable absorber, and SESAM mode-locking has been applied successfully to many of these lasers.

Sources Based on Nonlinear Frequency Conversion

Laser sources alone are unable to provide ultrashort pulses continuously tunable from the ultraviolet to the mid-infrared, and large gaps exist at wavelengths where no broadband laser materials are available. Harmonic generation using Ti:sapphire can be used to access some parts of the visible and ultraviolet regions, but infrared and certain visible wavelengths cannot be generated in this way and coverage is limited by the ability to tune the source itself. The nonlinear production of infrared wavelengths requires parametric down-conversion using a synchronously pumped optical parametric oscillator. Ti:sapphire pumped synchronously pumped optical parametric oscillators have produced, either directly or using harmonic generation, outputs from the green to beyond 7 μm.

Sources of Amplified Ultrashort Pulses

Modern ultrafast oscillators can produce pulses with peak powers of >1 MW, average powers of several watts, and cavity frequencies from 4 MHz to 2 GHz, but many applications require pulses with higher intensities or lower pulse repetition frequencies. Additional amplification stages can be used to satisfy these requirements and these are commonly

implemented in Nd:glass for picosecond pulses and Ti:sapphire for femtosecond pulses. In order to avoid damage and unwanted nonlinear effects caused by high pulse intensities within the amplifier system, most practical sources now apply the chirped-pulse amplification (CPA) approach in which a low-energy femtosecond seed pulse is stretched to sub-nanosecond durations to reduce its peak power then amplified and finally compressed to its original duration. Using the chirped-pulse amplification technique, pulses with peak powers as high as 1.5 petawatt have been generated.

Two possible amplifier geometries are used which are categorized either as multipass or regenerative amplifiers. In the multipass configuration the injected pulse is refocused many times through the same gain crystal using a system of mirrors. The gain crystal is pumped above the saturation fluence in order to extract the maximum stored energy from the medium per pass. The multipass geometry is more commonly used for high-average-power operation and critical alignment is required to maximize the overlap between the pump mode profile and the multiple beams intersecting the gain medium. The alternative regenerative amplifier is essentially a stable laser resonator which includes a Pockel cell and a polarizing beamsplitter to enable pulses to be switched into and out of the cavity. The gain per pass is considerably lower than in the multipass configuration but regenerative systems produce superior beam quality and their performance can be optimized without affecting the beam pointing of the output. Commercially available Ti:sapphire amplifiers commonly use the regenerative method and are available with pulse energies of up to 1 mJ at repetition frequencies in the 1–300 kHz range.

Pulse Characterization Techniques

D J Kane, Southwest Sciences, Inc., Santa Fe, NM, USA

Introduction

Ultrashort optical pulses have very short time durations, typically less than a few tens of picoseconds. As a result, these pulses are spectrally broad. Because the index of refraction of materials is a function of wavelength, different wavelengths of light travel at different speeds in optical materials, causing the properties of ultrashort optical pulses to change as they propagate. However, the shape of the pulse can influence how the pulse itself interacts with materials. Thus, the goal of ultrafast laser pulse measurement is to obtain not only the intensity profile of the pulse, but also the actual variation of the frequencies that make up the pulse. This is called measuring the intensity and phase of the pulse, respectively.

Even though the development of techniques to characterize ultrashort optical pulses has not been easy, a myriad of pulse measurement techniques have been developed. In this chapter, we will confine our discussion to the most well-known pulse and generally accepted pulse characterization methods in an effort to provide a basic working knowledge of pulse measurement techniques and a fundamental understanding of the principles behind pulse measurement. After a brief discussion of the mathematical representation of ultrashort optical pulses, we will discuss pulse measurement in (roughly) chronological order, starting with autocorrelation methods. The next section introduces a useful method for the measurement of the relative phase between two pulses called spectral interferometry (SI). Following SI, we introduce the notion of the time-frequency

representation of ultrashort optical pulses where techniques such as frequency-resolved optical gating (FROG) are discussed. Following the time-frequency section, a relatively new technique known as spectral phase interferometry for direct electric field reconstruction (SPIDER) is discussed.

Mathematical Representation of an Optical Pulse

The time-dependent variations of the pulse are embodied in the pulse electric field, $A(t)$, which can be written:

$$A(t) = \mathrm{Re}[E(t)\mathrm{e}^{\mathrm{i}\omega_0 t}] \quad [1]$$

where ω_0 is the carrier frequency and Re refers to the real part. While we can use $A(t)$ as it stands for calculations, it is much easier to remove the rapidly varying ω_0 part, $\mathrm{e}^{\mathrm{i}\omega_0 t}$, and use a slowly varying envelope together with a phase term that contains only the frequency variations, not the rapidly varying carrier frequency:

$$E(t) = [I(t)]^{1/2}\mathrm{e}^{\mathrm{i}\varphi(t)} \quad [2]$$

where $I(t)$ and $\varphi(t)$ are the time-dependent intensity and phase of the pulse. (Note that $E(t)$ is complex.) The frequency variation, $\Omega(t)$, is the derivative of $\varphi(t)$ with respect to time:

$$\Omega(t) = -\mathrm{d}\varphi(t)/\mathrm{d}t \quad [3]$$

The pulse field can be written equally well in the frequency domain by taking the Fourier transform of eqn [2]:

$$\tilde{E}(\omega) = [\tilde{I}(\omega)]^{1/2}\mathrm{e}^{-\mathrm{i}\phi(\omega)} \quad [4]$$

where $\tilde{I}(\omega)$ is the spectrum of the pulse, and $\phi(\omega)$ is its phase in the frequency domain. The spectral phase contains time versus frequency information; that is, the derivative of the spectral phase with respect to frequency yields the time arrival of the frequency – the group delay.

Obtaining the intensity and phase, $I(t)$ and $\varphi(t)$ (or $\tilde{I}(\omega)$ and $\phi(\omega)$ is called full characterization of the pulse. Common phase distortions include linear chirp, where the phase (either the time domain or frequency domain) is parabolic. When the frequency is increasing in time, the pulse is said to have positive linear chirp; negative linear chirp is when the high frequencies lead the lower frequencies. Higher-order chirps are common, but for these, differentiation between spectral and temporal chirp is required because spectral phase and temporal phase are not interchangeable.

Autocorrelation

Traditionally, we measure events using shorter events. Unfortunately, for the ultrafast researcher, shorter events do not exist and modern electronics are not fast enough. Therefore, because the shortest event we have is the event we wish to measure, traditional pulse measurement methods use the pulse itself to determine the approximate duration of the pulse in question giving birth to the ubiquitous intensity autocorrelation (see **Figure 1**). While autocorrelations cannot be used to fully characterize ultrashort optical pulses, the methods used in autocorrelations are fundamental to all pulse measurement schemes.

The intensity autocorrelation is measured by combining a pulse and a delayed replica of a pulse in a nonlinear medium such as a second harmonic generation (SHG) crystal. A pulse is sent onto a beamsplitter to produce the two replicas. One pulse is delayed relative to the other and both are focused together into a SHG crystal. As the delay of one pulse relative to the other is varied, the intensity of the second-harmonic signal is recorded. The intensity autocorrelation is not limited to using SHG; any nonlinearity may be utilized. Indeed, two-photon absorption in a semiconductor LED or photodiode often acts as a convenient nonlinearity. Sometimes a third-order nonlinearity is used to provide some direction of time information about the pulse. When the generation of the signal involves phase matching, such as second harmonic generation, care must be taken to use a thin crystal. Typically, 10 μm to 1 mm thick SHG crystals are used, depending on the bandwidth of the pulse to be measured. The exact thickness depends on the SHG crystal, the pulse width, and the requirements of the measurement.

Regardless of the nonlinearity used, an autocorrelation yields only the approximate duration and

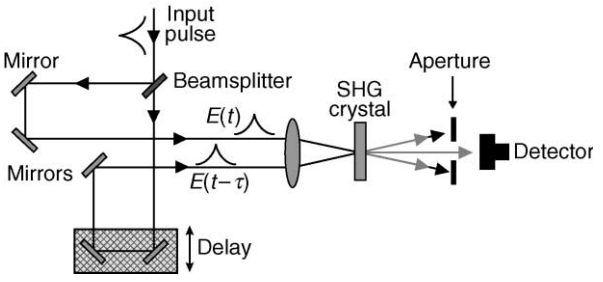

Figure 1 An intensity autocorrelator used to determine the approximate duration of a pulse. The pulse is split into two replicas that are sent into delay lines. The outputs from both delay lines are focused into a doubling crystal. The second harmonic output is monitored as a function of delay between the two pulses. A plot of the signal versus time is the intensity autocorrelation of the pulse.

shape of the pulse. The structure of the pulse is smeared, producing a smooth, featureless profile for even a complex pulse. Thus, the intensity autocorrelation alone does not determine the intensity profile of the pulse, $I(t)$. Only the interaction of the intensity of the pulse is recorded, producing no phase information for the pulse. Some qualitative information can be gleaned from the spectrum and the autocorrelation, but usually only that the pulse is chirped, and higher-order chirps and complex pulse structures elude such an analysis.

Another useful form of intensity autocorrelation is the single-shot autocorrelator. In this case, fairly large beams are used, and these beams are set to intersect at an angle of 2Φ, tilting the pulse fronts, so that delay is mapped onto a spatial coordinate (see **Figure 2**). The beams are then focused into a nonlinear medium using a cylindrical lens. The interaction region in the SHG crystal is imaged onto a linear array or CCD camera. Typically, when second-harmonic generation is used, the SHG crystal is oriented for Type I phase matching. The time window is proportional to $\Delta w(\sin \Phi)/\Delta v_g$, where Δw is the beam waist at the SHG crystal, and v_g is the group velocity of the pulse in the crystal. Like all SHG interactions, care must be exercised to insure that the phase matching is sufficient to mix the entire bandwidth of the pulse.

Jean-Claude Diels improved the intensity autocorrelation by the development of the interferometric autocorrelation. In this configuration, a Michelson interferometer is typically used so that the beams are collinear when arriving at the SHG crystal, which allows the beams to interfere. As a result, fringes appear on the autocorrelation. By examining the shape and extent of the fringes, some information about the pulse chirp can be obtained. While this does add to the information provided by an intensity autocorrelation, the added information is only the spectrum of the second harmonic. Unfortunately the addition of the second harmonic spectrum does not provide enough information for full retrieval of the intensity and phase.

Even though autocorrelation alone does not completely determine pulse intensity and phase, it is a very simple and useful technique to determine approximate pulse duration. Sometimes, cross-correlation can be used to determine the duration of a long pulse, if a shorter one is available, or a pulse too weak (or at an inappropriate wavelength) to measure with autocorrelation. The addition of the spectrum and/or the second harmonic spectrum can provide more,

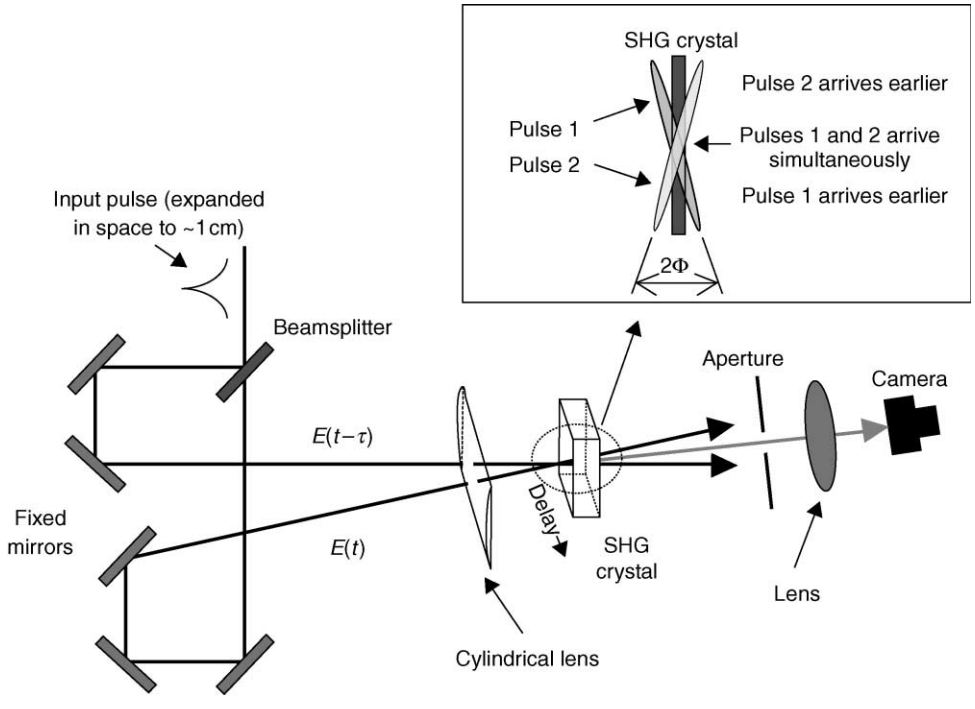

Figure 2 A single shot intensity autocorrelator. For this type of autocorrelator, the beam size is large, on the order of 1 cm in diameter, and the pulse fronts are tilted with respect to each other in order to map relative delay to position. The two beams are focused using a cylindrical lens and the output is recorded using an array detector. The inset shows how delay is mapped into position. Inset: the tilted pulse fronts cause time delay to be mapped spatially.

albeit, incomplete information about pulse chirp. More importantly, the experimental techniques used by correlation methods are fundamental to all pulse measurement methods.

Spectral Interferometry – Relative Phase Measurements

While determination of the absolute intensity and phase of an ultrashort laser pulse is difficult, determination of the relative phase is not. Invented in the late 1800s, spectral interferometry (SI), measures the relative phase between two pulses. SI, a linear technique, can also be modified (albeit, a some-what complex modification) to be self-referencing for full characterization of the ultrashort optical pulse (See the section on SPIDER below). In addition, when combined with a full pulse characterization technique, SI, because it is a linear technique, provides a method by which very weak optical pulses can be characterized (see below).

Typically, an SI apparatus uses a Mach–Zender interferometer (see Figure 3). A pulse is split into two replicas; one is sent through a region or medium to measure and the other through a known path. The two pulses remain separated by some known time and are sent, collinearly, into a spectrometer; no time scanning is required. An analysis of the fringe pattern yields the relative phase between the two pulses. In other words, SI provides $\phi_{\text{unk}}(\omega) - \phi_{\text{ref}}(\omega)$, where $\phi_{\text{unk}}(\omega)$ is the unknown pulse phase versus frequency. The spectrum of the two pulses in the frequency domain is

$$\tilde{I}_{\text{SI}}(\omega) = |\tilde{E}_0(\omega) + \tilde{E}_{\text{unk}}(\omega)|^2$$

$$\tilde{I}_{\text{SI}}(\omega) = \tilde{I}_0(\omega) + \tilde{I}_{\text{unk}}(\omega) + 2\sqrt{\tilde{I}_0(\omega)}\sqrt{\tilde{I}_{\text{unk}}(\omega)} \times \cos(\phi_{\text{unk}}(\omega) - \phi_0(\omega) - \omega\tau) \quad [5]$$

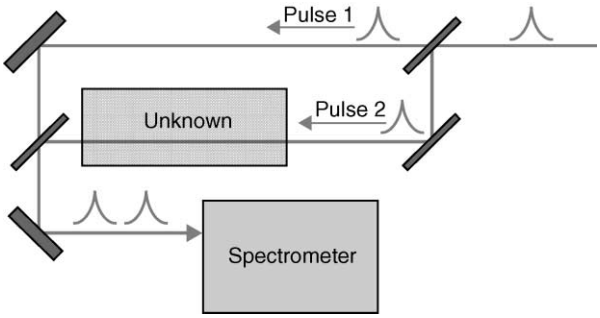

Figure 3 A Mach–Zender interferometer is the typical arrangement for spectral interferometry. One path acts as the reference arm and the sample to be measured is placed in the other arm. Unlike standard interferometry, the delay is fixed in a spectral interferometry experiment.

where $\tilde{I}_{\text{SI}}(\omega)$ is the output spectrum, $\tilde{E}_0(\omega)$ is the reference pulse electric field, $\tilde{E}_{\text{unk}}(\omega)$ is the unknown pulse electric field, $\tilde{I}_0(\omega)$ is the reference pulse spectrum, $\tilde{I}_{\text{unk}}(\omega)$ is the unknown pulse spectrum, $\phi_{\text{unk}}(\omega)$ is the unknown pulse phase, $\phi_0(\omega)$ is the reference pulse phase, and τ is the delay between the two pulses. To facilitate extracting the phase difference from the SI output, τ is chosen to yield fringes in the sum spectrum. The spectral fringes, which have a period inversely proportional to the optical path difference between the two beams (see Figure 4), contain all of the phase difference information.

Figure 4 shows the steps required to obtain the phase difference between the two pulses. The first step is to subtract out the spectra of the individual pulses in order to isolate the spectral interferogram, $S(\omega)$ (Figure 4a), where

$$S(\omega) = 2\sqrt{\tilde{I}_0(\omega)}\sqrt{\tilde{I}_{\text{unk}}(\omega)}\cos(\phi_{\text{unk}}(\omega) - \phi_0(\omega) - \omega\tau) \quad [6]$$

By Fourier transforming $S(\omega)$, we obtain

$$\Im^{-1}[S(\omega)] = f(t-\tau) + f(-t-\tau) \quad [7]$$

where $f(t)$ is the correlation product between the reference and the unknown electric field (see Figure 4b). The Fourier transform of eqn [7] multiplied by a Heaviside function, $\Theta(t)$ (to remove $f(-t-\tau)$), recovers the amplitude and phase of $f(\omega)$, the Fourier transform of $f(t-\tau)$, which contains the relative spectral phase between the unknown pulse and the unmodified pulse. Some care, however, needs to be taken to correctly remove the linear phase due to the time delay between the two pulses, $\omega\tau$. Also, for best results, the spectrometer should be well calibrated and care should be taken to properly window the spectrum before taking the Fourier transform.

Spectral interferometry is a straightforward and simple technique that always provides a relative phase. For this very reason, care must be taken to make sure the beams are mode-matched as well as collinear; also, interferometric stability must be maintained over the course of the measurement. Furthermore, SI is nongating; that is, CW background in the laser can add to the interferogram, masking transient effects. Nevertheless, spectral interferometry is a useful technique that has been applied to the measurement of the linear and nonlinear spectral phase introduced by optical fibers. More recently, SI has been applied to phase-locking and to phase-resolved pump probe experiments.

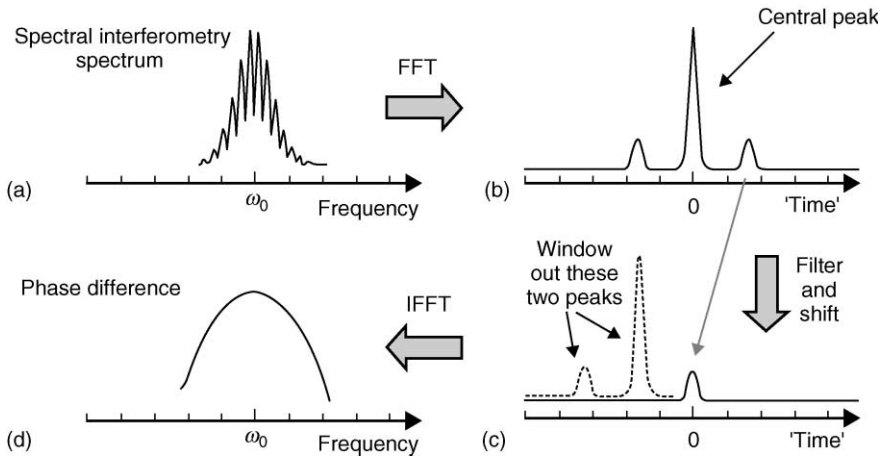

Figure 4 The steps required for the analysis of spectral interferograms. Part (a) shows a sample SI interferogram. The dominant frequency of the fringes is the delay multiplied by the speed of light. The actual phase differences of interest are the perturbations on this frequency. Part (b) is the Fourier transform of the SI interferogram in Part (a). (Note that this is not the true time domain.) The central peak contains only spectral information. All of the phase information is contained in the satellite peaks. The next step is to mask out the central peak and one of the satellite peaks (Part (c)). The phase of the inverse Fourier transform of Part (c) yields the relative phase between the two pulses (Part (d)).

Time-Frequency Representation

In 1971, E.B. Treacy laid the foundations for a revolution in pulse measurement by introducing the idea of measuring the intensity versus time for different spectral splices of a pulse. Because his measurements provided both time and frequency information simultaneously, these measurements could be thought of as applying in a hybrid time-frequency domain. At first, this may seem confusing, but similar methods have been used to visualize sounds patterns (a musical score, for example) and speech. A time-frequency plot of this type, where spectral slices of a pulse are plotted versus time, is called a sonogram. The mathematical formalism of a sonogram is:

$$S_{\mathrm{E}}(\Omega, T) = \left| \int_{-\infty}^{\infty} \tilde{E}(\omega) h(\omega - \Omega) \mathrm{e}^{-\mathrm{i}\omega T} \mathrm{d}\omega \right|^2 \qquad [8]$$

where $\tilde{E}(\omega)$ is the electric field of the pulse to be measured in the frequency domain and $h(\omega - \Omega)$ is a frequency gate that varies with frequency. The magnitude squared of the inverse Fourier transform of spectral slices yields the sonogram.

In 1991, Chilla and Martinez showed that the sonogram could be used to reconstruct the full intensity and phase of the pulse. That is, under certain conditions, the approximate group delay could be determined as a function of frequency from the sonogram by finding the peak time arrival of each spectral slice; integration of the group delay yields the spectral phase, which together, with the pulse spectrum, provides the intensity and phase of the pulse in the frequency domain. They labelled this technique as frequency domain phase measurement (FDPM).

An experimental diagram of an FDPM apparatus is shown in Figure 5. The pulse is split into two replicas, and one of the pulse replicas is spectrally filtered. The spectrally filtered pulse is cross-correlated with the original pulse to find the 'time arrival' of the spectrally filtered pulse – defined as the peak of the cross-correlated pulse. Because the spectrally filtered pulse has a much longer time duration than the original pulse, the small perturbation caused by the finite length of the original pulse is neglected.

The main difficulty of the Chilla–Martinez method is that the frequency gate must be very narrow, reducing the filtered pulse energy significantly, which greatly reduces the measured signal strength. If the spectral phase is not well behaved, the filtered pulse may not be much longer than the original pulse. In addition, for a given frequency, the sonogram may have two or more peaks in time, that is, the group delay may not be a function. However, a method called 2D phase retrieval, discussed in the next section, can alleviate many of these issues.

A spectrogram is a relative of the sonogram. Rather than determining the time arrival of spectral slices of a pulse, a spectrogram is obtained when the spectrum of time slices of the pulse are measured. The spectrogram is experimentally much easier to obtain than the sonogram; however, the measured quantity is not

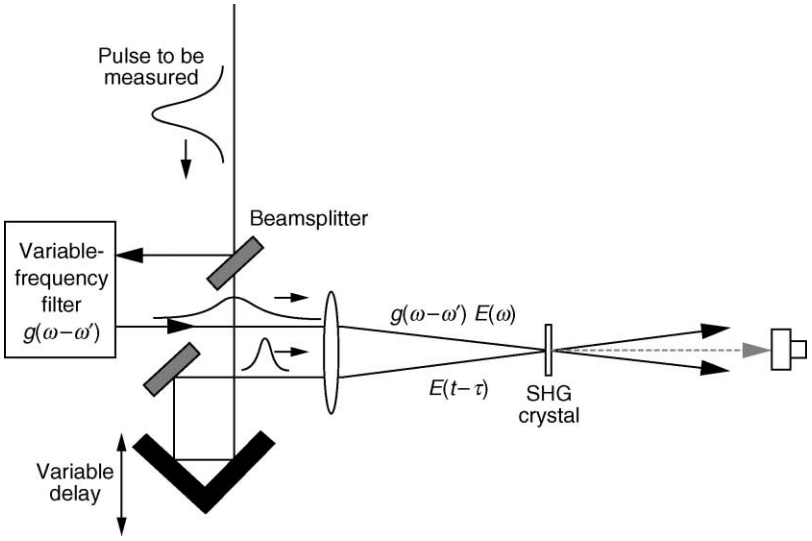

Figure 5 Measuring a sonogram requires determining the time arrival of spectral slices of the pulse. The pulse is split into two replicas using a beamsplitter. One replica is spectrally filtered using a tunable filter. The other pulse is cross-correlated with the spectrally filtered pulse to determine the time arrival.

quite as mathematically useful as the sonogram because the time slicing of the pulse occurs in the time domain. Thus, if a narrow time gate is used, the time domain phase is obtained. The time domain phase together with the intensity of the pulse, $I(t)$, provides the full intensity and phase of the pulse. Unfortunately, the intensity profile is not as readily measurable as the pulse spectrum. Consequently, to obtain the full intensity and phase of a pulse from its spectrogram requires an iterative 2D phase retrieval algorithm. This is the basis of a pulse measurement technique called frequency-resolved optical gating (FROG).

Frequency-Resolved Optical Gating

Frequency-resolved optical gating (FROG), developed by Kane and Trebino, measures the spectrum of a particular temporal component of the pulse (see Figures 6 and 7) by spectrally resolving the signal pulse in an autocorrelation-type experiment using an instantaneously responding nonlinear medium. As shown in Figure 6, FROG involves splitting a pulse and then overlapping the two resulting pulses in an instantaneously responding $\chi^{(3)}$ or $\chi^{(2)}$ medium. Even though any instantaneous nonlinear interaction may be used to implement FROG, perhaps the most intuitive is the polarization-gating configuration. In this case, induced birefringence, due to the electronic Kerr effect, is used as the nonlinear-optical process. In other words, the 'gate' pulse causes the $\chi^{(3)}$ medium, which is placed between two crossed polarizers, to become slightly birefringent. The polarization of the 'gated' probe pulse (which is cleaned up by the first polarizer) is rotated slightly by the induced birefringence allowing some of the 'gated' pulse to leak through the second polarizer. This is referred to as the signal. Because most of the signal emanates from the region of temporal overlap between the gate pulse and the probe pulse, the signal pulse contains the frequencies of the 'gated' probe pulse within this overlap region. The signal is then spectrally resolved, and the signal intensity is measured as a function of wavelength and delay time τ. The resulting trace of intensity versus delay and frequency is a spectrogram, a time- and frequency-resolved transform that intuitively displays time-dependent spectral information of a waveform.

The spectrogram can be expressed as:

$$S_{\mathrm{E}}(\omega,\tau) = \left| \int_{-\infty}^{\infty} E(t) g(t-\tau) \mathrm{e}^{-\mathrm{i}\omega t} \mathrm{d}t \right|^2 \qquad [9]$$

where $E(t)$ is the measured pulse's electric field, $g(t-\tau)$ is the variable-delay gate pulse, and the subscript E on S_{E} indicates the spectrogram's dependence on $E(t)$. The gate pulse $g(t)$ is usually somewhat shorter in length than the pulse to be measured, but not infinitely short. This is an important point: an infinitely short gate pulse yields only the intensity $I(t)$ and conversely, a CW gate yields only the spectrum $I(\omega)$. On the other hand,

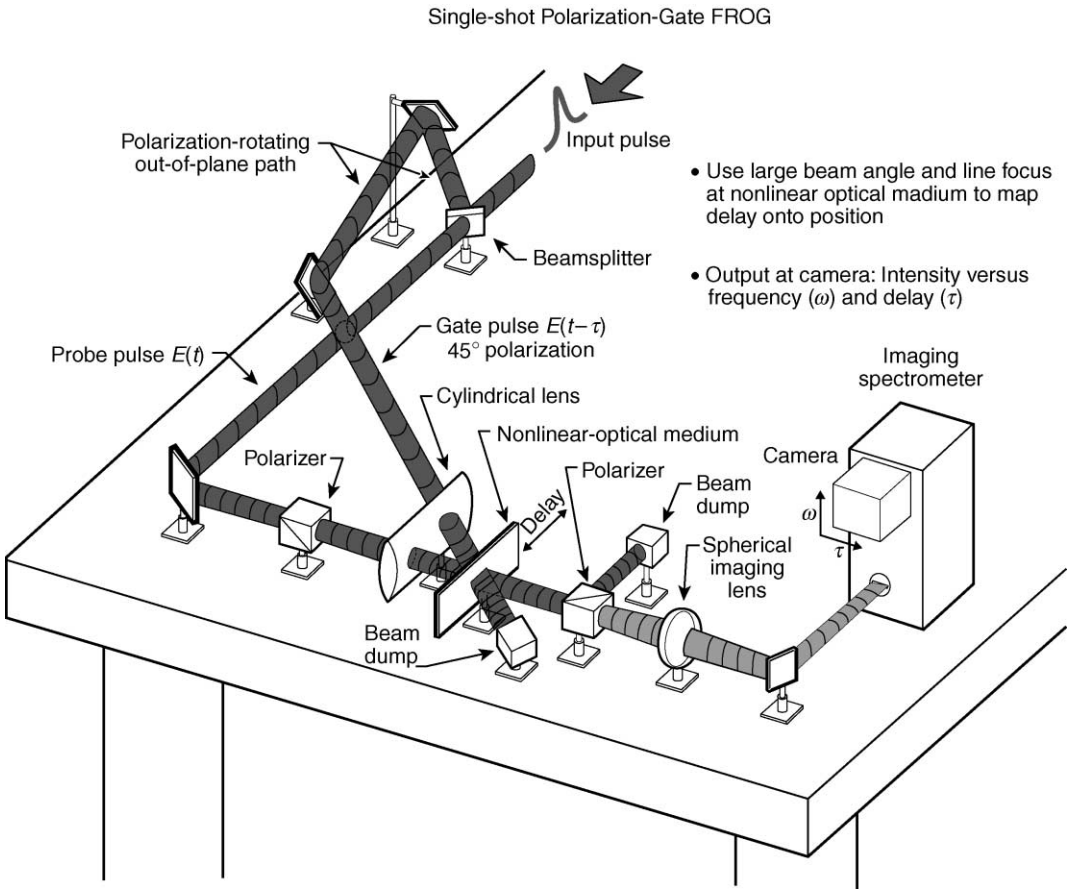

Figure 6 Measuring the spectrogram of a pulse is easier than measuring its sonogram – a spectrogram is a spectrally resolved autocorrelation. In this figure, the optical Kerr–effect is used (polarization-gate) as the nonlinearity. (Adapted with permission from Kane DJ and Trebino R (1993) Single shot measurement of the intensity and phase of an arbitrary ultrashort pulse by using frequency-resolved optical gating. *Optics Letters* 18(10): 823–825.)

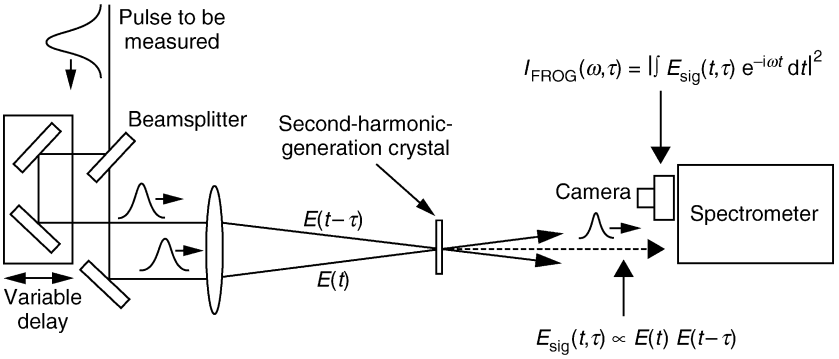

Figure 7 This figure shows a schematic of an SHG FROG device. The SHG signal from the autocorrelation is spectrally resolved. SHG FROG is very simple and sensitive, but it has a direction-of-time ambiguity. For example, if the pulse has chirp, only the magnitude of the chirp is determined – the sign of the chirp remains unknown.

a finite-length gate pulse yields the spectrum of all of the finite pulse segments with duration equal to that of the gate. While the phase information remains lacking in each of these short-time spectra, having spectra of an infinitely large set of pulse segments compensates for this loss. The spectrogram has been shown to nearly uniquely determine both the intensity $I(t)$ and phase $\varphi(t)$ of the pulse, even if the gate pulse is longer

than the pulse to be measured (although if the gate is too long, sensitivity to noise and other practical problems arise).

In FROG, when using optically induced birefringence as the nonlinear effect, the signal pulse is given by:

$$E_{\text{sig}}(t,\tau) \propto E(t)|E(t-\tau)|^2 \qquad [10]$$

So the measured signal intensity $I_{\text{FROG}}(\omega,\tau)$, after the spectrometer is:

$$I_{\text{FROG}}(\omega,\tau) = \left|\int_{-\infty}^{\infty} E(t)|E(t-\tau)|^2 e^{-i\omega t}dt\right|^2 \qquad [11]$$

We see that the FROG trace is a spectrogram of the pulse $E(t)$ although the gate, $|E(t-\tau)|^2$, is a function of the pulse itself.

To see that the FROG trace essentially uniquely determines $E(t)$ for an arbitrary pulse, it is first necessary to observe that $E(t)$ is easily obtained from $E_{\text{sig}}(t,\tau)$. Then it is simply necessary to write eqn [11] in terms of $E_{\text{sig}}(t,\Omega)$, the Fourier transform of the signal field $E_{\text{sig}}(t,\tau)$, with respect to delay variable τ. We then have what appears to be a more complex expression, but one that will give us better insight into the problem:

$$I_{\text{FROG}}(\omega,\tau) = \left|\int_{-\infty}^{\infty} E_{\text{sig}}(t,\Omega)e^{-i\omega t - i\Omega\tau}dt\,d\Omega\right|^2 \qquad [12]$$

Equation [12] indicates that the problem of inverting the FROG trace $I_{\text{FROG}}(\omega,\tau)$, to find the desired quantity $E_{\text{sig}}(t,\Omega)$, is that of inverting the squared magnitude of the two-dimensional (2D) Fourier transform of $E_{\text{sig}}(t,\Omega)$. This problem, which is called the 2D phase-retrieval problem, is well known in many fields, especially in astronomy, where the squared magnitude of the Fourier transform of a 2D image is often measured. At first glance, this problem appears unsolvable; after all, much information is lost when the magnitude is taken. It is well known that the one-dimensional (1D) phase retrieval problem is unsolvable (for example, infinitely many pulse fields give rise to the same spectrum). Intuition fails in this case, however; two- and higher-dimensional phase retrieval essentially always yields unique results.

The Simplified FROG – GRENOUILLE

A simplified version of the FROG device, known as grating eliminated no-nonsense observation of ultrafast incident laser light e-fields (GRENOUILLE), can be constructed using the doubling crystal as both the gating medium and the spectrometer (see Figure 8). In this case, the phase matching condition in certain thick doubling crystals causes a wavelength dependent output from the doubling crystal. A cylindrical lens is used in a Fourier transform configuration to image the wavelength variation onto a CCD camera. A cylindrical lens set at 90 degrees to the Fourier transform lens images the time axis onto the CCD camera. A Fresnel biprism replaces the traditionally used Mach–Zender interferometer to produce two pulses propagating at an angle with respect to each other. Presently, the GRENOUILLE technique works with BBO, in the wavelength region around 500 nm–1200 nm, and with proustite in the wavelength region around 1200 nm–2000 nm.

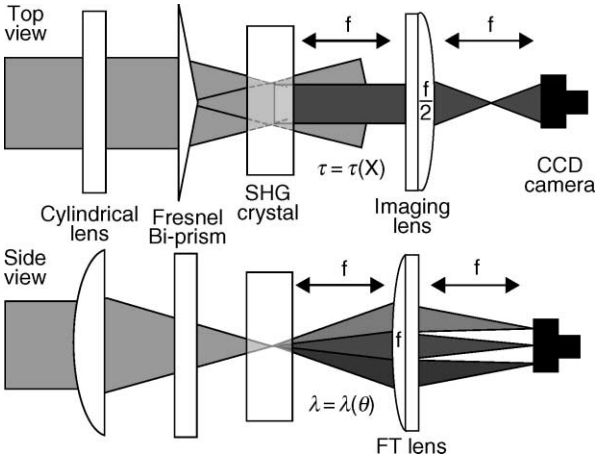

Figure 8 Figure showing a schematic of a GRENOUILLE FROG device which uses a thick doubling crystal as both the gating nonlinearity and the spectrometer. Like single-shot autocorrelators, a cylindrical lens focuses a spatially large input beam into an SHG crystal in only one dimension. Unlike most autocorrelators, the Mach–Zender interferometer is replaced with a Fresnel biprism that forces each half of the input beam to propagate, at an angle, toward the SHG crystal. An imaging cylindrical lens images the spatial dependence of the delay onto a CCD camera. A Fourier transform cylindrical lens maps the angular dependence of wavelength from the SHG crystal to a spatial coordinate on the CCD camera. FROG Inversion Algorithms

An iterative 2D phase retrieval algorithm is required to extract the pulse information from the measured FROG trace (see Figures 9 and 10). This algorithm converges to a pulse that minimizes the difference

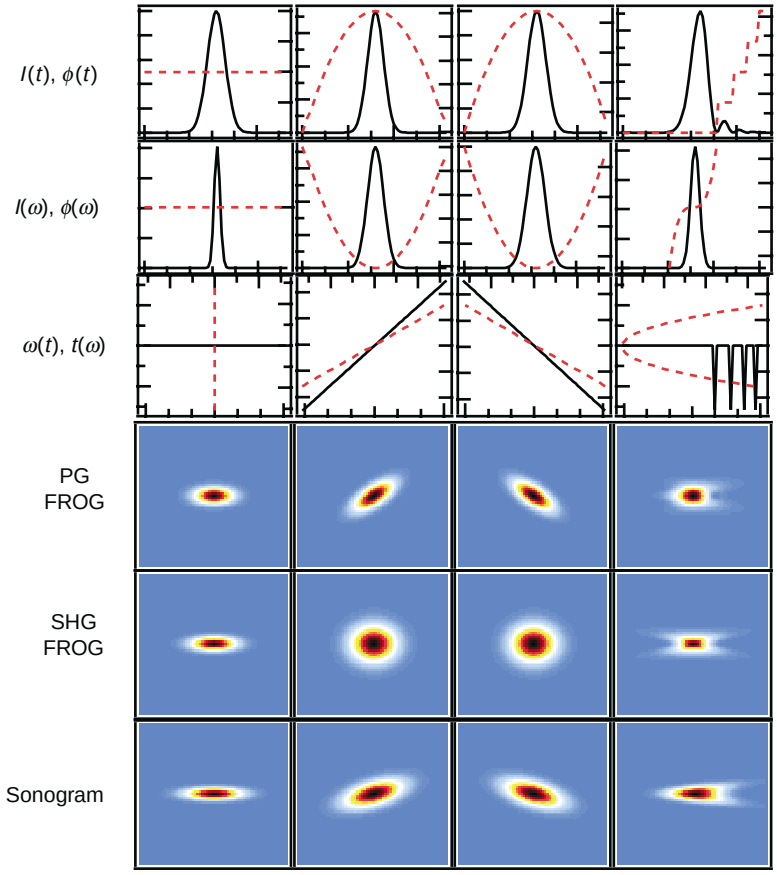

Figure 9 Example FROG traces and sonograms are shown for four different pulses: a transform limited pulse, a positively chirped pulse, and a negatively chirped pulse. The top series of plots are the time domain representation of the pulse intensity (solid line) and phase (dashed line). The second row of four plots is the frequency domain representation of the sample pulse's intensity and phase. The next four plots show the instantaneous frequency and the group delay. The vertical axis is frequency and the horizontal axis is time. The remaining rows show the PG FROG traces, the SHG FROG traces and sonograms of the pulse shown in the first two rows.

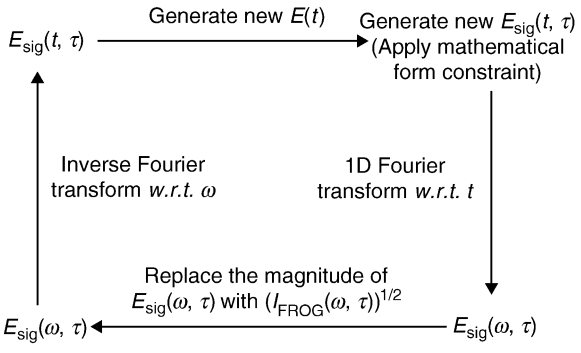

Figure 10 Phase retrieval algorithm for the inversion of FROG spectrograms. Start with an initial guess for the pulse to generate an initial $E_{sig}(t,\tau)$. A 1D Fourier transform generates the FROG trace. The next step is to replace the magnitude of the calculated FROG trace with the square root of the measured FROG trace. Inverse Fourier transform with respect to ω to produce the new signal field and generate a new guess for $E(t)$. Interestingly, it is only the step that produces $E(t)$ from $E_{sig}(t,\tau)$ that differentiates all the FROG algorithms.

between the measured and the calculated FROG trace. While this aspect of FROG has been its Achilles heel in the past, in reality, new generalized projections algorithms (together with faster computers) converge quickly and can track pulse changes at rates up to 30 Hz and beyond, making FROG a true, real-time pulse measurement technique. Indeed, excellent algorithms for the analysis of FROG traces in real-time are commercially available.

The original FROG inversion algorithm, commonly referred to as the vanilla algorithm, is simple and iterates quickly, but tends to stagnate, giving erroneous results, especially for geometries that use a complex gate function such as SHG or self-diffraction. An improved algorithm, incorporating several different algorithms including brute force minimization, was developed to alleviate stagnation programs at the expense of both speed and convergence time. By the mid-1990s, a significant

advance in both speed and stability was made by the addition of a numerical method called generalized projections. This algorithm determines the next guess by constructing a projection – minimizing the error (distance) between the FROG electric field, $E_{\text{sig}}(t, \tau)$, obtained immediately after the application of the intensity constraint, and the FROG electric field calculated from the mathematical form constraint.

The first generalized projections algorithm used a standard minimization procedure to find the electric field for the next iteration, which can still be slow. For the most common FROG geometries, PG and SHG, a different algorithm that determines the next iteration directly has been developed. This algorithm, called the principal components generalized projections (PCGP) algorithm, converts the generalized projections algorithm into an eigenvector problem. Using this algorithm, pulse measurement rates of at least 30 Hz have been achieved.

The goal of the phase retrieval algorithm is to find the $E(t)$ that satisfies two constraints. The first is the FROG trace itself which is the magnitude squared of the 1D Fourier transform of $E_{\text{sig}}(t, \tau)$:

$$I_{\text{FROG}}(\omega, \tau) = \left| \int_{-\infty}^{\infty} E_{\text{sig}}(t, \tau) \mathrm{e}^{-\mathrm{i}\omega t} \mathrm{d}t \right|^2 \qquad [13]$$

The other constraint is the mathematical form of the signal field, $E_{\text{sig}}(t, \tau)$, for the nonlinear interaction used. The signal forms for a variety of FROG beam geometries are:

$$E_{\text{sig}}(t, \tau) \propto \begin{Bmatrix} E(t)|E(t-\tau)|^2 & \text{PG FROG} \\ E(t)^2 E^*(t-\tau) & \text{SD FROG} \\ E(t)E(t-\tau) & \text{SHG FROG} \\ E(t)^2 E(t-\tau) & \text{THG FROG} \end{Bmatrix} \qquad [14]$$

where PG is polarization gate, SD is self-diffraction, SHG is second harmonic generation, and THG is third harmonic generation FROG.

All FROG algorithms work by iterating between two different data sets: the set of all signal fields that satisfy the data constraint, $I_{\text{FROG}}(\omega, \tau)$, and the set of all signal fields that satisfy eqn [14]. The difference between the FROG algorithms is how the iteration between the two sets is completed. In the case of generalized projections, the $E(t)'$s are chosen such that the distance between the $E(t)$ on the magnitude set and the $E(t)$ on the mathematical form set is minimized. This is accomplished by minimizing the following equation:

$$Z = \sum_{i,j=1}^{N} \left| E^{(k)}_{\text{sig(DC)}}(t_i, \tau_j) - E^{(k+1)}_{\text{sig(MF)}}(t_i, \tau_j) \right|^2 \qquad [15]$$

where $E^{(k)}_{\text{sig(DC)}}(t_i, \tau_j)$ is the signal field generated by the data constraint, and $E^{(k+1)}_{\text{sig(MF)}}(t_i, \tau_j)$ is the signal field produced from one of the beam geometry equations in eqn [14]. For the normal generalized projection, the minimization of Z is completed using a standard steepest descent algorithm; the derivative of Z with respect to the signal field is computed to determine the direction of the minimum. The computation of the derivatives are tedious; they are tabulated elsewhere.

An alternative to an algorithm that minimizes eqn [15] is the PCGP algorithm. This algorithm converts the computation of the next guess into an eigenvector problem, reducing the computation of the next guess to simple matrix–vector multiplications. This algorithm works for both the PG and SHG beam geometries, it is robust and the fastest FROG algorithm. Indeed, the PCGP algorithm was used in the original real-time FROG work by D.J. Kane.

Self Checks in FROG Measurements

Unlike any other pulse measurement techniques, FROG can provide a great deal of feedback about both the quality of the measurement (systematic errors) and the quality of the algorithm's performance. The most common check for convergence is the FROG trace error together with a visual comparison between the retrieved FROG trace and the measured FROG trace. The FROG trace error is given by:

$$G = \sqrt{\frac{1}{N^2} \sum_{i,j=1}^{N} \left| I_{\text{FROG}}(\omega_i, \tau_j) - \alpha I^{(k)}_{\text{FROG}}(\omega_i, \tau_j) \right|^2} \qquad [16]$$

where α is a renormalization constant, I_{FROG} is the measured trace, and $I^{(k)}_{\text{FROG}}(\omega, \tau)$ is computed from the retrieved electric field. Typically, the FROG trace error of a PG measurement should be less than 2% for a 64×64 pixel trace, while the FROG trace error of a 64×64 pixel SHG FROG trace should be about 1% or less. Acceptable FROG trace errors decrease as FROG trace size increase for smaller FROG traces. These values are only rules of thumb only;

for example, acceptable retrievals of large and very complicated FROG traces can produce larger FROG trace errors.

In a good FROG measurement, the spectrum of the retrieved pulse should faithfully reproduce the salient features of the pulse's measured spectrum. SHG FROG even provides an additional check called the frequency marginal. The sum of an SHG FROG trace along the time axis yields the autoconvolution of the pulse's spectrum, providing two ways the FROG measurement can be checked. First, the autoconvolution of an independently measured spectrum can be compared to the sum of the FROG trace along the time axis, providing an indication of how well the measurement was made. For example, if the doubling crystal was too thick in the pulse measurement, the FROG trace's frequency marginal will be narrower than the autoconvolution of the measured spectrum. Second, comparing the autoconvolution of the retrieval pulse spectrum with the FROG trace marginal can provide a test of algorithm convergence in addition to a test of the measurement. Phase matching problems appear as a mismatch between the FROG trace frequency marginal and the autoconvolution of the retrieved spectrum.

Because FROG is a spectrally resolved autocorrelation, summing any FROG trace along the frequency axis yields the autocorrelation of the measured pulse. This autocorrelation can be compared to an independently measured autocorrelation, or a comparison can be made between the frequency sum of the FROG trace and the autocorrelation calculated from the retrieved pulse to determine algorithm convergence and the quality of the measurement.

Measuring Pulses Directly – SPIDER

SPIDER is a novel technique that measures the pulse directly – no iterative phase retrieval method is required. To accomplish this feat, spectral interferometry is conducted on two pulse replicas that are shifted in frequency with respect to one another. The original pulse is split into two replicas. The two pulse replicas are sent into a phase modulator that shifts the center frequency of each pulse slightly. The frequency-shifted pulses are sent into a spectrometer and a standard spectral interferometry analysis yields the derivative of the phase. Integration of the phase derivative, together with the spectrum of pulse, provides the full intensity and phase.

Thus, analysis of the spectral interferogram gives:

$$\Delta\phi = (\phi(\omega_1) - \phi(\omega_2))\Delta\omega \qquad [17]$$

where $\Delta\phi$ is the measured phase difference from the spectral interferogram, $\Delta\omega$ is the difference in the center frequency between the two pulses, and $\phi(\omega)$ is the pulse phase as a function of frequency. Consequently, the phase difference must be divided by the frequency difference between the two pulses to determine the true derivative. It is also important to subtract out the linear phase difference resulting from the delay between the two pulses (the delay produces the fringes in the resulting interferogram) as this integrates to a linear chirp.

Because phase modulators are too slow to be used in the femtosecond region, a different method is used to shift the frequency of the two pulses – they are mixed with a highly chirped pulse (see Figure 11).

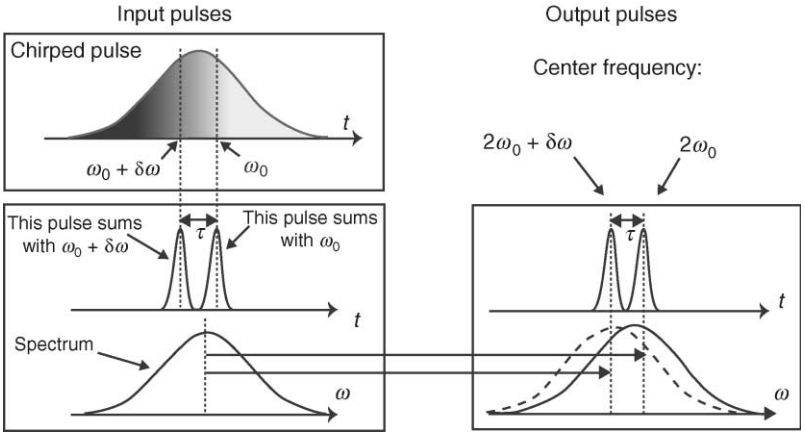

Figure 11 Figure showing how a SPIDER device works. The highly chirped pulse has a frequency that varies with time. Mixing the chirped pulse with two time delayed replicas produces two pulses, separated in time, that have slightly different frequencies, but are otherwise identical. By interfering the two pulses in a spectrometer, the relative phase between $\omega_0 + \delta\omega$ portions of the pulse and ω_0 portions of the pulse are determined.

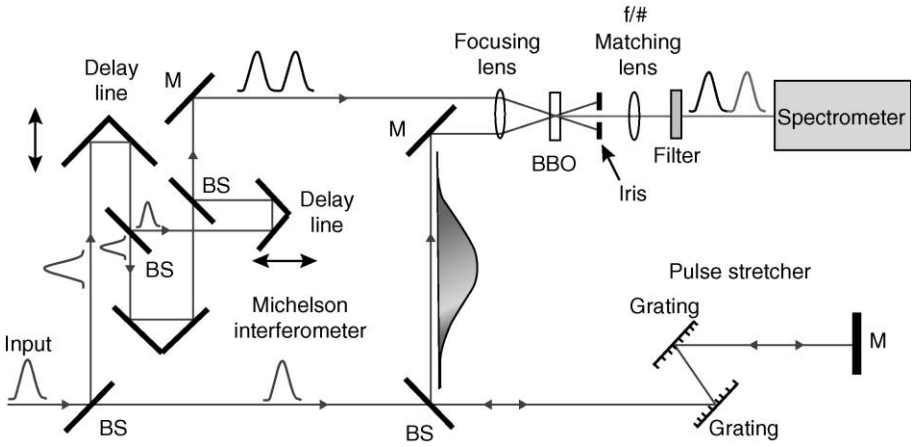

Figure 12 SPIDER apparatus. The input pulse is first split into two pulses. One pulse is stretched in a pulse stretcher. The other pulse is sent into a Michelson interferometer to produce two time-delayed pulses. The two time-delayed pulses are mixed with the stretched pulse to produce two pulses at a slightly different center frequency. The two pulses are sent into a spectrometer to produce a spectral interferogram. Analysis of the spectral interferogram yields the derivative of the pulse phase.

Because the pulses are slightly time delayed, each one aligns with a slightly different frequency in the chirped pulse. The chirped pulse must be so highly chirped that the pulse frequency does not change significantly over the duration of the pulse to be measured.

A schematic of a SPIDER device for the measurement of femtosecond laser pulses is shown in Figure 12. The input pulse is first split into two replicas. The first replica is sent to a pulse stretcher to produce to highly chirped pulse. The other replica is sent into a Michelson interferometer (or a simple étalon may sometimes suffice) to create two time-delayed replicas. The time-delayed replicas are mixed with the chirped pulse. Because each replica is mixed with a slightly different frequency in the chirped pulse, each replica produces a pulse with a slightly different center frequency. When the time-delayed replicas are spectrally resolved, each frequency of the pulse interferes with a frequency-shifted portion of the same pulse. Thus, the measured phase difference is proportional to the derivative of the phase of the original pulse.

Measuring Weak Pulses

Because virtually all the pulse measurement techniques, that do not require a reference pulse, use a nonlinearity, measuring weak ultrafast pulses directly is difficult. Fortunately, because most weak pulses are generated from a stronger pulse, spectral interferometry can be used to determine the relative phase between the weaker pulse and the stronger pulse (for regions where there is spectral overlap between the two pulses). If the stronger pulse is characterized using another pulse measurement technique, then the weaker pulse phase can be determined from the relative phase measurement and the known phase of the stronger pulse. For example, the Trebino group termed the combination of FROG and SI as TADPOLE (Temporal Analysis by Dispersing a Pair Of Light E-fields).

Which Pulse Measurement Method Should I Use?

Choosing a pulse measurement method depends on the required measurement as well as the precision and accuracy required. All the pulse measurement techniques have advantages and disadvantages, but excellent measurements have been made with all of them. Autocorrelation is adequate when all that is required is the approximate pulse duration without any phase information. Spectral interferometry is quite useful for measuring transient changes in a sample in pump-probe experiments. FROG is perhaps the most commonly used and general-purpose pulse measurement technique, providing a great deal of feedback about the quality of the pulse measurement. Inexpensive and convenient FROG devices, together with software, are available commercially, adding to their acceptance. While SPIDER is experimentally complex and does not have the cross checks that FROG has, it provides the quickest answer, requiring no iterative

phase retrieval algorithm to obtain pulse intensity and phase.

List of Units and Nomenclature

$A(t)$	Full electric field
$E(t)$	Complex electric field without carrier frequency
$E_{\text{sig}}(t, \tau)$	Complex electric field of the FROG trace versus time and time delay
$E_{\text{sig}}(t, \Omega)$	Fourier transform of $E_{\text{sig}}(t, \tau)$ with respect to τ
$\tilde{E}(\omega)$	Complex electric field in the frequency domain
$f(t)$	Correlation product
$f(\omega)$	Fourier transform of the correlation product
$g(t-\tau)$	time gate or filter
G	FROG trace error
$h(\omega-\Omega)$	frequency gate or filter
$I(t)$	Intensity profile of the electric field in the time domain
$\tilde{I}(\omega)$	spectral intensity
$I_{\text{FROG}}(\omega, \tau)$	Intensity of the FROG trace
$\Theta(t)$	Heaviside function $= 0\ t < 0,\ = 1\ t \geqq 0$
$\phi(\omega)$	Frequency domain phase
$S_{\text{E}}(\omega, \tau)$	Spectrogram
$S_{\text{E}}(\Omega, T)$	Sonogram
$S(\omega)$	Spectral interferogram
t, T	variables for time
τ	Fourier transform
v_{g}	group velocity
$\varphi(t)$	Time domain phase
Δw	Beam waist
Z	Distance metric between the FROG signal field generated by the data constraint and the FROG signal field generated by the mathematical form constraint
Φ	Geometric angle between two beams
$\Delta\phi$	Phase difference
$\Pi^{(n)}$	nth order nonlinear susceptibility
ω	Primary variable for frequency
$\Delta\omega$	Difference in center frequency between two pulses
Ω	Secondary variable for frequency
$\Omega(t)$	Instantaneous frequency

Introduction

Chemical reactions are at the heart of chemistry; the quest to understand them has sparked research and study along many different avenues. The fundamental dynamics involved in bond breakage, bond formation, and transition states take place on a very fast time-scale, usually in the tens to hundreds of femtoseconds, where a femtosecond (fs) is equal to 10^{-15} seconds. Therefore, ultrashort laser pulses are required to measure these fundamental processes as well as the rotational and vibrational motion before and after the reaction. The whole set of measurements can then be used for mapping a potential energy surface for the reaction. As a result of these studies, one learns the key details that are required to develop a picture of how chemical reactions occur. The measurement of these fundamental dynamics, using ultrashort laser pulses, is the subject of this article.

To illustrate how long it takes to form or break a chemical bond, one needs to consider the following analogy. The time it takes to break a chemical bond is approximately a tenth of a trillionth of a second (10^{-13} s). During such a short time, light can travel only 0.03 mm in vacuum. This time is so short that it cannot be measured electronically. Its measurement requires the use of ultrashort laser pulses, with pulse durations of 50 femtoseconds or shorter. The development of methods aimed at measuring the fundamental steps involved in chemical reactions culminated in the development of femtosecond transition state spectroscopy (FTS), a method developed in the 1980s by Zewail and co-workers at Caltech. This work allows researchers to observe bond breakage and formation, vibrational and rotational dynamics, and transition state configurations, as the reaction occurs. The Nobel Prize in Chemistry was awarded in 1999 to Ahmed Zewail for this development. Since the 1980s, femtosecond lasers have been used to study molecular dynamics and chemical dynamics on very fast time-scales. The field, known as femtochemistry, has grown quickly and diversified to involve hundreds of scientists around the world. This article discusses the measurement of ultrafast dynamics measured in gas-phase samples. The presentation encompasses some of the measurement techniques and the fundamental values to be measured and concludes with an outlook towards the future.

From Nanosecond to Picosecond to Femtosecond Reaction Kinetics

The quest for shorter light pulses to study chemical reactions predates the invention of the laser. In the early days, electric discharges were used to measure fast dynamics in the millisecond (10^{-3} s) and then the microsecond (10^{-6} s) time-scales. With the invention of the laser, measurements improved drastically with temporal resolution going from the nanosecond (10^{-9} s) to the picosecond (10^{-12} s) time-scales. Since the early days, it was recognized that the best time resolution was obtained when pairs of light pulses were used – one to initiate the reaction and the second to probe it. These pump-probe measurements have progressed with the laser technology almost to the single femtosecond level.

The measurements being considered here go beyond the measurement of fast reaction kinetics. When a chemical reaction occurs in a beaker, one usually measures a statistical rate of reaction that involves diffusion of reagents in a solvent. These kinetic measurements, which involve an ensemble of molecules, are much slower and do not reveal the

fundamental steps of the reaction such as bond formation. The introduction of ultrafast pulses allowed, for the first time, the measurement of the motion of the atoms in real time, as if the motion was frozen by ultrafast flash photography. Capturing this motion helps to reveal the internal forces, described by a potential energy surface, that act on the atoms in the molecule during the chemical reaction. This concept is illustrated in Figure 1, where we see the reagents and the products for the reaction. Typically, the starting and ending point of a chemical reaction are very well known and the compounds are very well characterized. However, how the reagents become the products is not always known. Chemists typically deduce a reaction mechanism based on a large body of experiments where different parameters including the structure of the reagents are modified to evaluate their effect on the outcome of the reaction. Unfortunately in most cases, reaction mechanisms, even when consistent with all available experimental evidence, may not accurately reflect how a particular chemical reaction takes place.

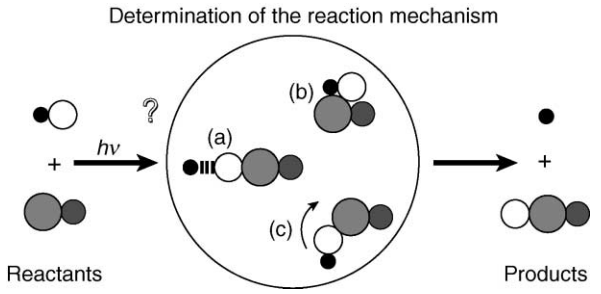

Figure 1 A sketch of a chemical reaction, AB + CD → A + BCD. The reactants and products are well known, but it is not known how they change from reactants to products. This mechanism may involve a transition state which is (a) a linear complex with vibrational motion, (b) a nonlinear complex, (c) a bent complex with rotational motion, or many other possibilities and combinations. The elucidation of the mechanism and transition state dynamics are the goals of femtosecond time-resolved studies.

The ideal method to make the determination involves direct observation. As mentioned earlier, direct observation requires femtosecond laser pulses, just like a fast camera shutter is required to take pictures of fast-moving objects. The concept of a femtosecond pump-probe measurement is illustrated in Figure 2. The chemical reaction is initiated at time $t = 0$ fs by the pump laser. The pump laser provides the energy required for initiating the chemical transformation. The probe laser, delayed in time, probes the formation of the product. Figure 2 illustrates a number of pump-probe measurements

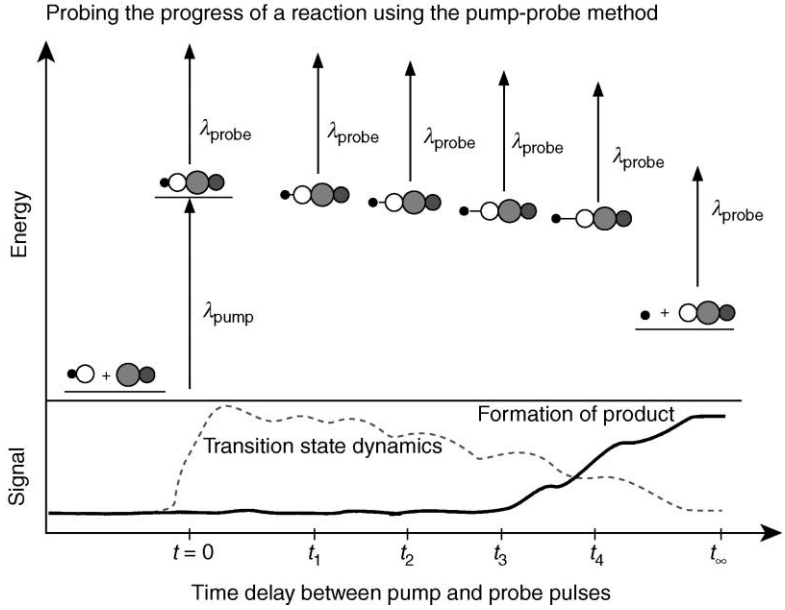

Figure 2 Energy schematic of the reaction of AB + CD → A + BCD assuming vibrational motion in a linear transition state. The pump pulse provides enough energy to excite the reactants to the transition state at $t = 0$. This transition state is probed by the second pulse. This pulse arrives at different time delays, from no delay ($t = 0$), to increasing delays (t_1, t_2,…), to infinite delay (t_∞). The signal varies depending on the time delay between the two pulses and these changes in signal intensity correspond to vibrational and rotational information about the transition state. To obtain a transient as shown at the bottom, the time delay between the pump and probe pulses is scanned. The dashed line shows the transient that would be obtained when the transition state is monitored; the solid line shows the transient that would be obtained when the product is monitored.

each obtained at a different time delay between the pump and probe laser pulses. When a series of pump-probe measurements are gathered as a function of time delay, one obtains a transient that contains a record for the evolution of the reagents to product as a function of time.

The Formation of Coherent Wave Packets and their Motion

The illustration shown in Figure 2 shows atoms in a molecule moving as classical particles. Because of their small size, atoms behave quantum mechanically and this has some implications on the observed motion. A prototypical pump-probe measurement is illustrated for this purpose in Figure 3. For resonant excitation, a photon is absorbed by a molecular system, originally in the ground electronic state (V_0). This absorption causes a vertical transition to an excited electronic state (V_1). Consistent with Heisenberg's uncertainty principle, a pulse that has a short temporal duration has a large spectral bandwidth; for most molecular systems and ultrashort pulses, the frequency spread of the pulse is wider than the vibrational energy spacing in the excited state. Thus, a number of quantum vibrational states are populated on V_1 by the absorption of a short laser pulse. When a short pulse excites a number of states, a coherent superposition of states is formed. One can understand the formation of a wave packet by simply realizing that in the short time the laser pulse excites the system there is no opportunity for the atoms in the molecule to move. For this reason the initial wave packet is very similar to the ground state atomic arrangement.

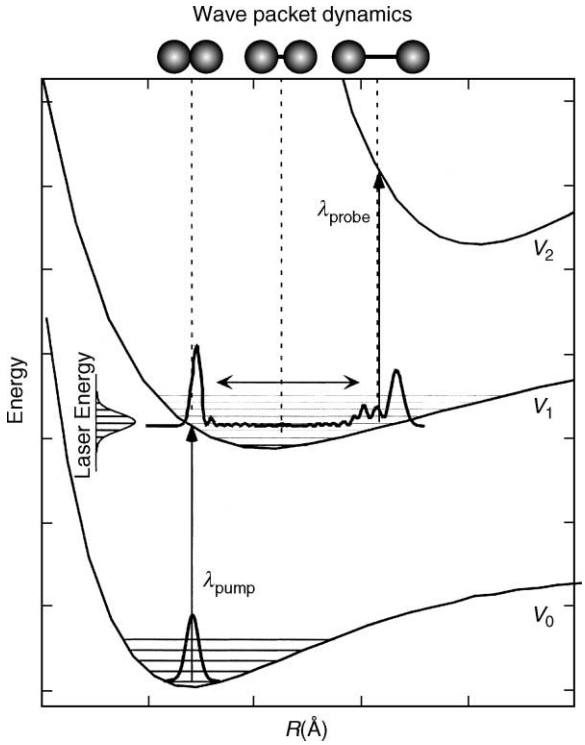

Figure 3 Pump-probe experiment. The pump pulses excite the molecular system from the ground state V_0 to excited state V_1. The large spectral bandwidth of femtosecond pulses allows for a number of vibrational levels in V_1 to be populated. A wave packet is formed that vibrates on V_1; the classical motion of the particle is shown as well at the top. In this case the energy of the probe pulse will excite the molecules to V_2 when the bond is stretched (right side of oscillation); however, when the bond is compressed, the energy is not resonant with any excitation and the probe pulse will not be absorbed.

When a short laser pulse excites a molecule to a bound electronic state, the resulting wave packet, $\Psi(t)$, is a sum of all the possible states φ_n in V_1 with amplitudes, a_n, $\Psi = \sum_n a_n \varphi_n$. The amplitudes, a_n, depend on the overlap between the initial (ground state) and final (excited state) spatial overlap. This overlap indicates that the excitation process is faster than the motion of atoms in a molecule. Based on this approximation for the overlap integral, the amplitudes are replaced by the Franck–Condon overlaps to obtain $\Psi = C\sum_n \langle \varphi_n | \varphi_0^{(0)} \rangle \varphi_n$. The wave packet on V_1 evolves in time according to $\Psi(t) = \sum_n a_n \exp[-iE_n t/\hbar]\varphi_n$, where E_n is the energy that corresponds to the state φ_n and $\hbar$ is Planck's constant divided by 2π. When a pulse is very short in time, the coherent superposition of states closely resembles the initial distribution of atoms in the molecule. The motion from inner to outer turning point of the quantum mechanical wave packet is illustrated in Figure 3. One can imagine this wave packet as a classical particle oscillating on the excited potential energy curve with the periodic nature of the molecular vibrations. When the pulse is very long and only one state is populated, the dynamics can no longer be observed, as is the case with conventional frequency-resolved spectroscopy.

Molecular dynamics can be inferred from high-resolution frequency-resolved spectroscopy; however, the spectra can become congested and the data analysis becomes more complicated for large molecules, for high temperatures, or in solutions. Molecular dynamics are obtained from frequency-resolved spectra by taking the Fourier transform of the data. It seems more intuitive to consider these dynamics in the time domain where the dynamics can be observed directly as 'snapshot' taken by the femtosecond pulses. Ultrafast time-resolved spectroscopy has other advantages – high peak intensities allow for multiphoton excitation and other nonlinear processes, the selection of the detection wavelength discriminates between different species and results in

an increased signal-to-noise ratio for intermediate short-lived species, collisions take place on a longer time-scale and do not affect these measurements, and the characteristics of the ultrafast laser pulse (such as phase, frequency components, and chirp) can be manipulated to control the dynamics and the yield of chemical reactions.

Methods for Measuring Femtosecond Dynamics

Pump-Probe Method

Pump-probe techniques use a pair of pulses separated in time, one to initiate the reaction and the second to determine its progress. The first femtosecond pulse with wavelength λ_{pump} excites a molecule from its (bound) ground electronic state (V_0) to an excited (V_1) state. After a variable time delay, a second femtosecond pulse with wavelength λ_{probe} causes a transition to another excited state (V_2) as shown in Figures 3 and 4.

The progress of the reaction dynamics is followed through the measurement of signal resulting from the absorption of the probe pulse by the system. There are different detection modes depending on the potential energy surfaces reached by the pump and probe pulses. In one case (Figure 4a), the first excited state (V_1) is nonfluorescent but the second one (V_2) fluoresces and this fluorescence is measured. In another case (Figure 4b), state V_1 is fluorescent but state V_2 is not; in this case the depletion of the fluorescence by the probe is measured. Finally (Figure 4c), excited states V_1 and V_2 may be dissociative; therefore, the fluorescence detected is emitted by the products. In any of these cases, as the wave packet on the intermediate state propagates (e.g., vibrates, dissociates), the transition probability varies (i.e., the ability of the probe pulse to be absorbed by the molecule changes). Therefore, the amount of laser-induced fluorescence (LIF) emitted varies with the pump-probe time delay. In some cases, the probe pulse produces ions and there are a number of methods to detect the electrons or the ions with great sensitivity.

Measurement of rotational dynamics

Measurement of rotational dynamics requires a vectorial frame of reference and this is achieved with linearly polarized laser beams. Excitation by the pump pulse selects an initial population distribution described by $\cos^2\theta$ where θ is the angle between the transition dipole and the pump laser polarization vector. As the rotational wave packet dephases due to the distribution of the population in different rotational levels, the probe pulse probes the transient alignment of the molecules in space. As the molecules rotate away from the initial alignment, the signal decreases. In Figure 5 rotational dynamics are depicted schematically. First, a single (classical) molecule is considered (top panel). As the molecule rotates, its dipole changes from being aligned with the polarization vector of the laser field

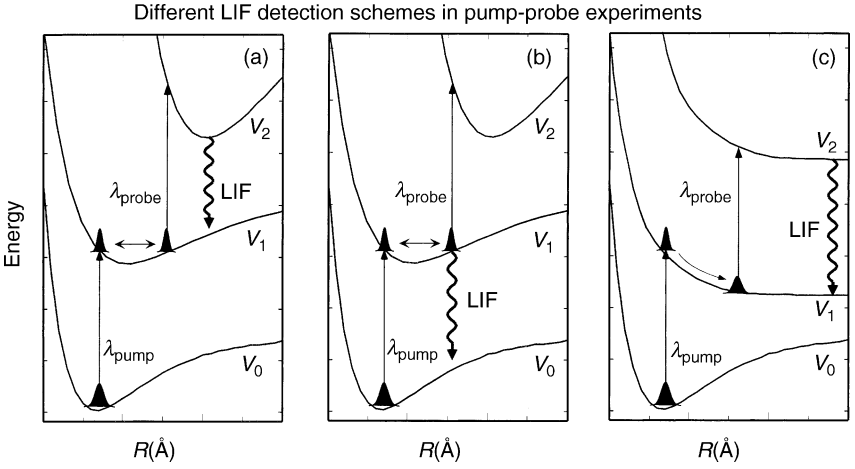

Figure 4 Different pump-probe experiments.(a) Bound-to-bound transitions from $V_0 \rightarrow V_1$ and from $V_1 \rightarrow V_2$. The V_2 state fluoresces and this increase in LIF from V_2 is measured as signal. (b) Bound-to-bound transition from $V_0 \rightarrow V_1$ where V_1 fluoresces. When the probe pulse causes an excitation from $V_1 \rightarrow V_2$, a loss of LIF signal is observed. The depletion of fluorescence is measured in this case. (c) Bound-to-repulsive surface transition from $V_0 \rightarrow V_1$. The energy of the probe causes an excitation to V_2 at a particular molecular distance. Fluorescence of a product fragment is measured.

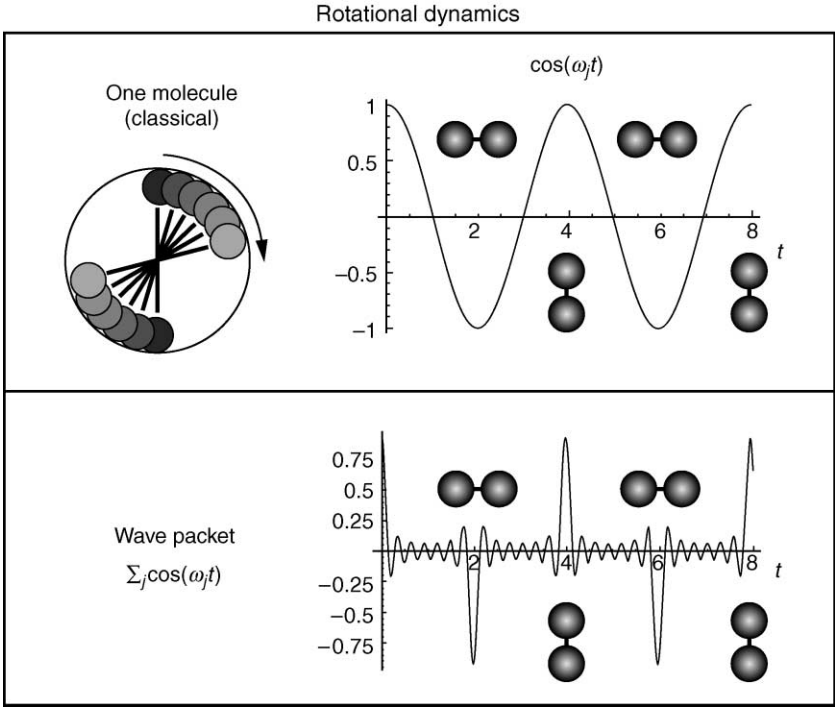

Figure 5 Rotational motion of molecules. Excitation by a linearly polarized laser pulse initially selects molecules that are well aligned ($\cos^2\theta$) with its polarization. Considering only one molecule evolving in time (top), the rotational motion in the molecule causes it to move away from the initial alignments and then eventually return to it. The signal will decrease when the molecule is not aligned with the polarization of the probe laser and will increase when aligned well. The signal looks like a cosine function that depends on the rotational frequency of the molecule (ω_j). For a rotational wave packet, the rotational dynamics are similar except that a number of rotational levels are populated; thus, the signal depends on the summation of many cosine functions and the features in the data become sharper.

(assumed vertical) to being perpendicular. The rotational motion can be described by a cosine function. The rotational frequency ω_j is proportional to the rotational level and the rotational constant of the molecule. Because the rotational constant is inversely proportional to the angular momentum, larger molecules rotate slower than smaller molecules. When several rotational levels are contained in a rotational wave packet the motion produces sharper features (bottom panel). The sharp features are called rotational recurrences or revivals. Note that the opposite trend is observed if the probe pulse is polarized perpendicular to the pump pulse; the signal increases as the molecules rotate away from the initial alignment and decreases as the alignment recurs. The time-resolved data for each polarization arrangement (parallel and perpendicular) contain both an isotropic component (vibrational motion) and an anisotropic component (rotational motion). In rotational anisotropy measurements, data from these two polarization arrangements are manipulated mathematically to yield just the rotational motion; rotational dynamics and rotational information such as the spectroscopic rotational constants and the rotational energy partitioning in the reactants and products can be extracted from these measurements.

Three-Pulse Four-Wave Mixing Method

Some methods are more complicated than pump-probe technique but they are more powerful. Three-pulse four-wave mixing (FWM) is one such method and is briefly presented here. Time-resolved four-wave mixing techniques can be understood based on the formation of transient gratings by two of the incident lasers. When two laser beams cross, the spatial modulation of their electric fields varies due to constructive and destructive interference as shown in Figure 6. The molecules in the interaction region experience varying electric field intensities according to their position and this leads to the formation of a transient grating of polarized molecules in space. The transient grating formation can be probed easily by the detection of Bragg scattering of a third laser beam, also known as homodyne detection; here, the signal beam is scattered in the phase-matching direction $\mathbf{k}_{\text{signal}}$ as indicated in Figure 6a. Alternatively, probing can be achieved by detection of changes in the intensity of a fourth beam that propagates in the

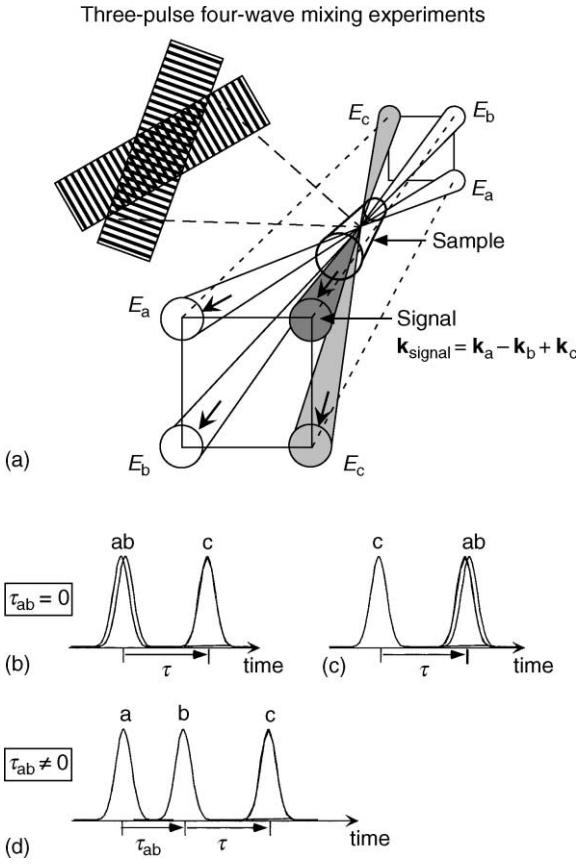

Figure 6 (a) FWM experimental configuration. Two of the beams cross which forms a grating and the third beam scatters off the grating to generate a fourth beam (the signal). The three laser pulses are noted as electric fields E_a, E_b, and E_c. These three laser pulses can be delayed or advanced in time relative to each other giving rise to a number of different pulse sequences. (b) Pulse sequence with fields E_a and E_b overlapped in time ($\tau_{ab} = 0$). Field E_c follows at a time delay τ. (c) Pulse sequence in which E_c precedes E_a and E_b by time delay τ. For both of these cases, τ is scanned in time to obtain the transients. (d) Pulse sequence in which no pulses are overlapped in time and are applied in the order E_a, E_b, and E_c. Time delay τ_{ab} can be set to specific values while τ is scanned in time.

same direction as the signal; this is called heterodyne detection. The medium that constitutes the gratings is composed of the sample molecules, which in the gas phase move freely. Therefore as time evolves, the molecular dynamics (rotation and vibration) modulate the transient grating and hence the signal.

Three-pulse four-wave mixing is a nonlinear spectroscopic method that combines the interaction of three laser pulses in a phase-matched geometry with a well-defined time sequence of the pulses. The signal from these measurements arises from a third-order polarization resulting from the interaction of the three electric fields. Three-pulse FWM is similar to the pump-probe technique in that a preparation step is followed, after some variable time delay, by a probing step. However, three-pulse FWM allows for a greater degree of control over the preparation and probing processes.

When the lasers are in resonance with an electronic state, FWM measurements can provide dynamic information from the ground and excited electronic states. When two pulses are incident on the sample at $t = 0$ and a third pulse probes the dynamics at a later time τ (as in Figure 6b), the measurements provide information that is very similar to that from a pump-probe measurement. However, having three pulses allows for other different setups. For example, when one pulse arrives at the sample first and the other two pulses follow after a time delay (as in Figure 6c), the resulting signal provides dynamic information from the excited state. This type of measurement also provides a measurement of the electronic coherence of the sample, i.e., for how long the molecules remember the phase of the incident laser pulses. This information is important if one wants to take advantage of the phase of laser pulses to cause quantum mechanical interference in the molecular sample. These measurements are known as photon echo and are much more common in condensed-phase samples. There are numerous pulse sequences possible; only three examples are shown in Figure 6.

FWM measurements do not depend on resonance excitation to an electronic excited state. In the absence of such resonance, the grating is formed in the ground state and ground state vibrational and rotational dynamics are observed. These measurements, also known as transient grating (TG), depend on the impulsive Raman scattering process. By changing the time delay (in Figure 6b) between the electric fields that generate the grating and the third (probe) beam, the signal is modulated by the molecular dynamics. Analysis of the time-dependent signal yields the rotational and vibrational spectroscopic values from the sample being studied.

Studies of Reaction Dynamics

Dissociation on a Repulsive Surface

In 1987, Zewail and co-workers studied the photodissociation of cyanogen iodide (ICN) using femtosecond lasers; the first direct observation of a chemical reaction from reactants to products was conducted. The excitation and decay of the reactants (ICN), the formation and decay of the intermediates (I–CN), and the formation of the products (I + CN) were observed in this experiment.

The pump pulse (306 nm) excited ground state cyanogen iodide to a repulsive excited state of ICN which dissociated into I and CN fragments (both in the ground state). The probe pulse when set to 388.5 nm was resonant with an excitation of the CN fragment; therefore, the reaction was monitored by detecting the laser-induced fluorescence (LIF) of this CN^* fragment using a probe pulse at different time delays (as shown in Figure 4c). The wavelength of the probe pulse could be detuned to different wavelengths for making observations at different lengths of the I–C bond. The results of these experimental studies showed that ICN dissociated in about 200 fs and that the transition state lived for only about 50 fs. The data from the wavelength detuning studies were used to map the excited state potential of ICN both in time and in space; this data analysis is called inversion to the potential.

A schematic representation of the ICN experiment is shown in Figure 7. The potential energy curves are shown in Figure 7a. The pump laser initiates the chemical reaction. Three different probe wavelengths are depicted, the first probing early in the reaction, the second at an intermediate distance, and the final one probing the free products. Notice that the wavelength of the probe determines the location in the potential energy curve that is probed. This concept allows one to study reagents as they are transformed into products. The signals obtained from the three different probe wavelengths are shown in Figure 7b.

Reactions Involving Crossing of Potential Energy Surfaces

For many chemical reactions, the progress of the reaction requires changes of the electronic state. This can take place where potential energy surfaces cross. The best-known example of reaction dynamics involves the experiment on the photodissociation of NaI by Zewail and co-workers. This experiment is depicted in Figure 8. The pump pulse excites the wave packet from ground state (ionic) to an excited state (covalent) where it begins to oscillate. The ground and excited states overlap with an avoided crossing in this molecule (ionic versus covalent nature, as shown in Figure 8a); when the wave packet approaches this avoided crossing, it splits into two partial waves. One wave stays on the excited state while the other 'escapes' onto the dissociative surface and separates into Na and I. The partial wave on the excited state again oscillates and then splits at the avoided crossing and the pattern continues. The time delay of the probe pulse shows the oscillations of the wave packet on the excited surface when detecting the activated complex $[NaI]^{*‡}$ (thin line), while the data of the product fragments (free Na atoms detected by using the D-line absorption) (thick line) show a step-wise accumulation in the signal corresponding to the sequential formation of products during each oscillation near the avoided crossing region of the surfaces (see Figure 8b).

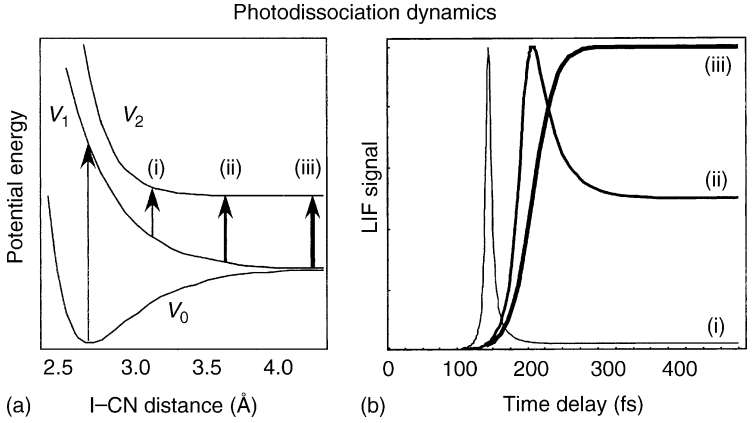

Figure 7 Photodissociation of ICN. (a) Potential energy surface schematic showing the initial excitation by the pump laser to a dissociative surface. The reaction could be monitored at different I–CN distances by using different probe wavelengths as shown by three examples here, (i), (ii) and (iii), from shorter to longer distances. (b) At short distances (long probe wavelengths), the signal is observed at shorter time delays only. The signal decreases at later time delays because the internuclear distance continues to lengthen as the dissociation occurs over time. When the distance increases as monitored by shorter probe wavelengths, the signal rises to a maximum at longer time delays reflecting the dissociation of the reaction in progress. At 'infinite' I–CN distance (i.e., the molecule is dissociated and only free I atoms and CN fragments remain), the signal reaches a maximum and remains there because the reaction is complete.

Chemical Dynamics with Multiple Pathways

The pump-probe concept can be used to probe more complex reactions. To date, a great number of different chemical reactions have been studied (see Further Reading). Among the most important reactions we list ring opening, isomerization, proton transfer, and concerted chemical reactions. We illustrate these measurements with experiments on the photodissociation of dihalogenated alkanes. Upon high-energy excitation (12 eV), the methylene iodide (CH_2I_2) molecule dissociates and forms molecular iodine in excited states D′ and f as well as producing I atoms (main channel). The detection wavelength used in the experiment can distinguish between these products; D′ fluorescence can be collected at 342 nm and f fluorescence is collected at 272 nm. The Dantus group has studied the dynamics of this type of concerted molecular elimination reaction extensively. The photodissociation reaction occurs by a multiphoton excitation (three-photons from the pump beam at 310 nm) reaching a dissociative state where the CH_2 fragment and excited molecular iodine are formed. The 620 nm probe pulse depletes the fluorescence from the excited I_2 molecule (either D′ or f state) as shown in Figure 4b; this fluorescence depletion is measured and analyzed to determine the dynamics of the reaction. The object of this experimental work was to determine if the photodissociation mechanism for forming molecular iodine followed a step-wise, synchronous concerted, or asynchronous concerted mechanism as shown in Figure 9.

The time transients reveal coherent vibrational motion of the I_2 product. Analysis of the transition state dynamics shows that the breaking of the carbon–halogen bond and the formation of the halogen–halogen bond occurs within 50 fs. Further, the iodine molecule is formed with a very hot rotational distribution indicating that the symmetry of the molecule is broken during the process; the torque imparts a large amount of rotational motion. Overall, the results of these studies show that the photodissociation process of CH_2I_2 follows an asynchronous concerted reaction mechanism and corresponds to a symmetry barrier that exists in C_{2v} molecules preventing the formation of the interhalogen bond. The existence of this symmetry barrier was explored by using CH_2ICl, a molecule that does not have C_{2v} symmetry; as expected, the halogen molecule (ICl) was formed with a cold rotational distribution indicating that it was able to follow a synchronous concerted mechanism. The dissociation times were also studied on the family of compounds CX_2Y_2 and $R{-}CHI_2$ to investigate the influence of thermodynamics and reduced mass changes on the reaction.

The Dynamics of Bond Formation

Most chemical reactions that are studied with femtosecond spectroscopy are unimolecular reactions (photodissociation); however, bimolecular reactions (photo-association) are interesting and chemically relevant in trying to understand how chemical reactions occur. In the photo-association process, a pair of atoms or molecules cooperatively absorbs the photon undergoing a free-to-bound transition and forming a bond. When the ultrashort pulse initiates the reaction in femtosecond photo-association spectroscopy, a clearly defined initial time for the reaction is given

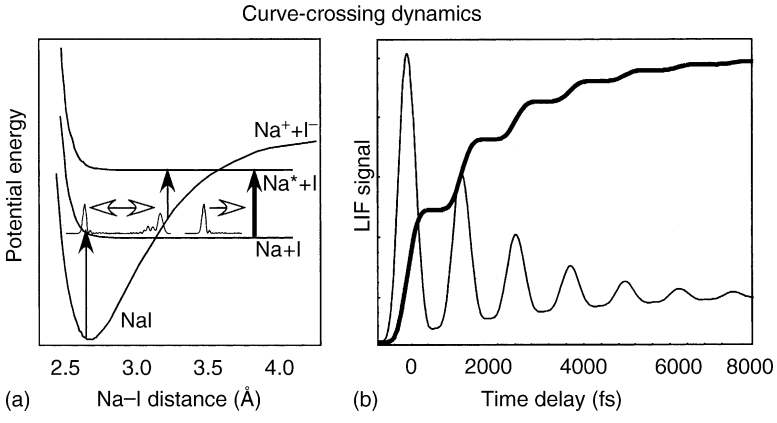

Figure 8 Photodissociation of sodium iodide. (a) Potential energy curve schematic showing the curve-crossing between the ground (ionic) and excited (covalent) states. As the wave packet oscillates on the excited curve, it splits into two wave packets at the curve crossing. (b) The thin line shows the vibrations of the excited complex as it oscillates on the excited surface. The signal intensity decreases because some of the molecules have dissociated to form Na and I atoms when the wave packet splits. The thick line shows the stepwise increase in free Na atom signal each time the wave packet oscillates and splits.

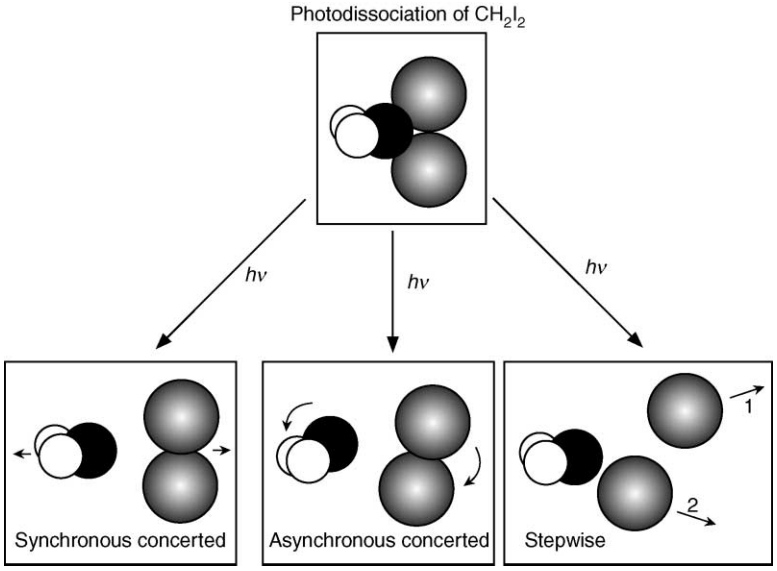

Figure 9 Possible mechanisms for the photodissociation of CH_2I_2 following multiphoton excitation. The molecule could break both C–I bonds and form an I–I bond all at the same time (synchronous concerted mechanism); this would result in very little rotational motion in the products. The molecule could begin to break one C–I bond slightly before breaking the second one and forming the I–I bond, but all three events still occur within the duration of the laser pulse (asynchronous concerted mechanism). This would result in significant rotational motion in the products. The molecule could also lose one I atom and at some later time lose the other I atom; these I atoms could collide later to form I_2 (stepwise mechanism).

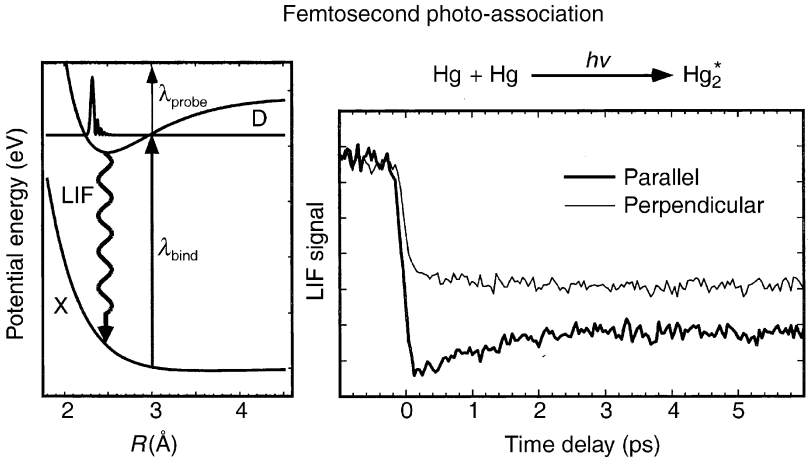

Figure 10 Photo-association of mercury dimers. The pump (bind) pulse is absorbed by two ground-state Hg atoms to form Hg_2^* on the excited state which is fluorescent. The probe pulse depletes this fluorescence causing the LIF signal to decrease at $t = 0$. Analysis of the transient reveals that the time of association is <60 fs. Parallel and perpendicular pump-probe data were examined to obtain the rotational distribution of this reaction.

and the alignment conditions of the reaction can be examined by taking advantage of the polarization of the lasers. The femtosecond photo-association spectroscopy technique was used by the Dantus group to study the formation of an excited mercury dimer. Their experiment is depicted in Figure 10. Two ground-state mercury atoms absorbed the pump (bind) pulse (at 312 nm) forming a wave packet in the excited D state. The probe pulse depleted the fluorescence from the newly formed molecules. The time of association was determined to be within the laser pulse duration (<60 fs). The dimers were found to have a narrow rotational distribution which together with the wavelength of the binding pulse reflects the impact parameter (geometry) of the collision. Calculations reveal that the 'optimal'

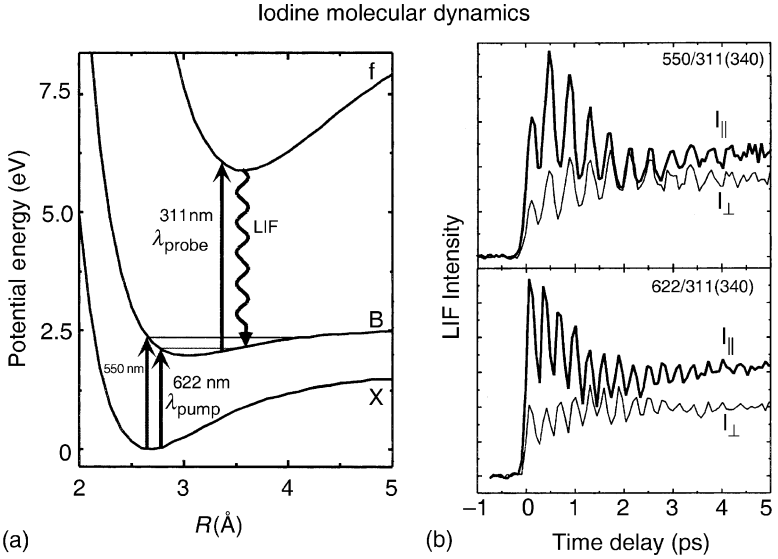

Figure 11 Molecular dynamics of iodine using two different pump laser wavelengths. (a) The pump laser, either at 550 or 622 nm, causes an excitation from the ground state to the B excited state. The choice of wavelength determines the vibrational levels which are excited on the B state. In either case, the probe at 311 nm causes an excitation to the f excited state which fluoresces around 340 nm. (b) Parallel and perpendicular pump-probe transients were obtained using each pump wavelength. At higher pump energies (550 nm), the molecule vibrates more slowly (higher vibrational level) and is reflected by the 410 fs vibrational period observed in the data. At lower pump energies (622 nm), the molecule vibrates faster and corresponds to the 300 fs vibrational period observed in the data.

binding pulse for this association reaction is 10 fs; such short pulses would overlap the entire absorption band from the repulsive ground state to the bound D state.

Bimolecular reactions can also be studied by preparing a low-temperature cluster that contains the reagents of interest. For example, a cluster containing one HI and one CO_2 molecule can be used to study the reaction $H + CO_2 \rightarrow OH + CO$. Initiation of the reaction takes place when the pump laser cleaves the H–I bond and the H atom attacks the CO_2 molecule present in the cluster. The reaction dynamics are probed as a function of time delay between pump and probe pulses as for other pump-probe experiments. The femtosecond dynamics of this reaction have been studied independently by Wittig's and Zewail's research groups.

Studies of Molecular Dynamics

I_2-Pump-Probe, Rotation and Vibration (Bound Surface)

Aside from observing chemical reactions, using ultrafast spectroscopy allows for studying the motion of isolated molecules to elucidate the internal motions of molecules themselves and to extract spectroscopic parameters. Iodine is one of the most frequently used molecules in femtosecond spectroscopy. Here we highlight only a small subset of the femtosecond studies on I_2 that have been conducted by Zewail's and other research groups. Using a pump beam at 550 nm, ground state I_2 is excited to the B state; probing with 310 nm excites the molecule to an even higher bound potential (f state) from which fluorescence at 340 nm can be obtained (as shown in Figure 11). By changing the pump-probe time delay, oscillations on the B excited state are clearly visible and show a vibrational period of approximately 410 fs. Excitation at 622 nm produces a wave packet lower in the potential well, with a vibrational period of approximately 300 fs. The differences observed for parallel and perpendicular probing correspond to the early rotational motion of the molecules. Fourier transfer analysis of the data yields the energy of each vibrational state that forms part of the vibrational wave packet. Different pump wavelengths can be used to access different vibrational levels such that vibrational frequencies and rotational constants can be obtained for a wide range of vibrational levels of the potential. This information can then be used to refine the B excited state potential energy curve of iodine.

Different Measurements Possible with Three-Pulse FWM

Ground and excited state molecular dynamics

Molecular dynamics can also be examined with four-wave mixing techniques. Once again we use iodine as a model system to illustrate that unlike the previous experimental transients of iodine obtained with pump-probe measurements, both excited and

ground state dynamics of I_2 are revealed with FWM. Materny, Kiefer, and co-workers have carried out coherent anti-Stokes Raman spectroscopy and degenerate four-wave mixing measurements on this molecule using two pulses overlapped in time followed by a third pulse after a time delay; both ground and excited state dynamic are observed in the Fourier transform of data. Dantus and co-workers explored all the pulse sequences possible with three-pulse FWM using molecular iodine as a model system (see below).

Double-sided Feynman diagrams and third-order response functions can be used to describe the interaction of the three pulses with the molecular system in three-pulse four-wave mixing. These mathematical tools are described in several books on nonlinear optical spectroscopy (see Further Reading). Figure 12 illustrates how different pulse sequences reveal different molecular dynamics. The transient grating method (Figure 12a) shows both ground (160 fs oscillations) and excited state (310 fs oscillations) wave packet dynamics. When data collection occurs over long time delays, the transient grating signal persists with a similar time constant to that of the lifetime of the excited state. The photon echo pulse sequence (shown in Figure 12b) reveals only excited state dynamics (310 fs oscillations). Note that at longer time delays, the signal decays exponentially with a time constant that reflects the rate of electronic coherence dephasing. This fundamental decay parameter indicates how long molecules remember the phase of the electric field that acted on them.

Off-resonance transient grating molecular dynamics

Off-resonance transient grating can be used to study the molecular motion of molecules in the ground state. The pulse sequence used is shown in Figure 6b. With this method it is possible to examine the rotational and vibrational dynamics of diatomic and polyatomic molecules. The vibrational dynamics belong to the Raman-active modes. From the rotational recurrences, one can obtain rotational constants with great accuracy. Dantus and co-workers have studied carbon dioxide at room temperature and in flames. At high temperatures, rotational recurrences narrow because more rotational levels are populated and the rotational recurrence moves towards longer times because of centrifugal distortion. Further studies on carbon dioxide and carbon disulfide have shown that strong fields can impart an increase in initial alignment (due to torque along the polarization vector of the laser) as well as molecular deformation such as bending (due to electronic state mixing). Heterodyne detected off-resonance transient grating data for CO_2 at room temperature are shown in Figure 13. The data closely resemble the schematic illustration in Figure 5 where rotational dynamics were introduced. The data in Figure 13 have been analyzed to yield the B and D rotational constants which give the structural parameters of the molecules and the centrifugal distortions, respectively. The type of analysis given here for CO_2 can be done on molecules

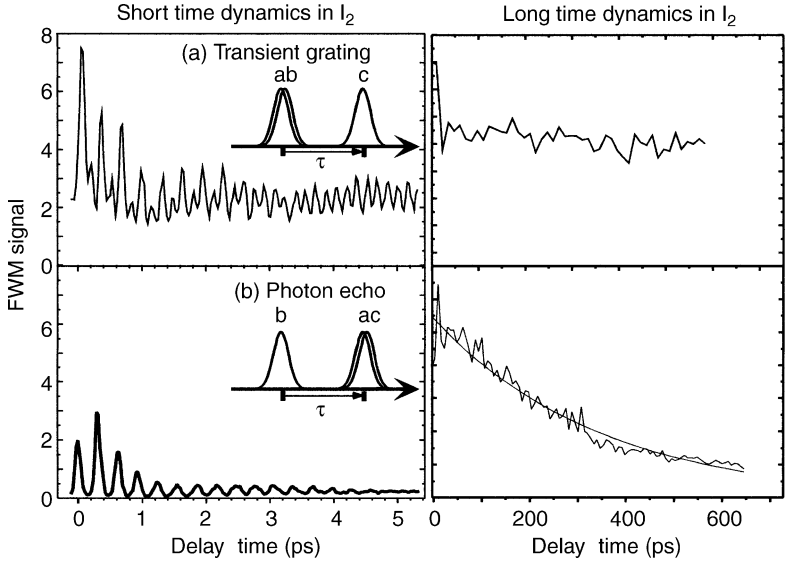

Figure 12 FWM signal in molecular iodine using two pulse sequences at short and long delay times. (a) Transient grating – E_a and E_b overlapped in time followed by E_c. Similar amounts of ground (208 cm^{-1}) and excited (105 cm^{-1}) state dynamics are observed with short delay times. In the transients, these correspond to oscillations of 160 fs and 307 fs respectively. (b) Photon echo – E_a and E_c overlapped in time but preceded by E_b. Excited state dynamics are observed in the transient with short delay times. At long time delays, the decrease in the signal reflects (a) the lifetime of the excited state or (b) the rate of the electronic coherence dephasing.

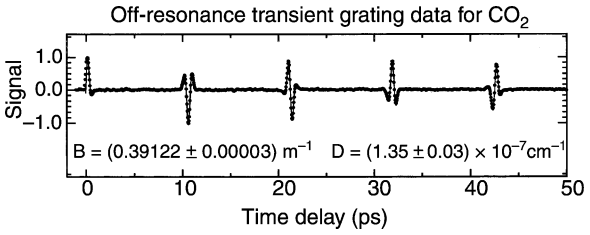

Figure 13 Heterodyne detected off-resonance transient grating on carbon dioxide at room temperature. The experimental data (dots) reflect the rotational motion of the CO_2 molecule. The data have been analyzed (the fit is shown as a line that goes through the experimental data points) to obtain the rotational constant (B) and the centrifugal distortion constant (D).

and molecular fragments resulting from chemical reactions. This method can also be used for molecular identification.

Perspectives for the Future

Most of this article has focused on the observation of ultrafast dynamics involved in chemical reactions. Presently, it is possible to generate pulses with durations as short as 5 fs. Such short pulses are capable of observing motion involving frequencies near 3000 cm^{-1}. This implies that one can observe the dynamics of most chemical bonds. The availability of shorter pulses will allow one to observe electronic dynamics. Advances in laser technology have also produced ultrashort pulses in the infrared region as well as in the vacuum ultraviolet and X-ray region. The wide spectrum available permits experiments that follow specific chemical bonds or specific transitions in elements. This in turn gives a wide range of possibilities for probing ultrafast chemical reaction dynamics.

Having pulses that are shorter than the duration of the dynamics they probe allows one to consider influencing the evolution of a chemical reaction as it is taking place. Controlling chemical reactions with lasers is not a new theme; however, the availability of ultrashort laser pulses has given new power to these efforts. Here we present a brief sample of some of the current efforts.

Control Using Three-Pulse Four-Wave Mixing

Coherent control of chemical reactions depends on the relative phase of two different laser pulses that interact with the sample in order to optimize the transfer of population between electronic states. The three-pulse four-wave mixi\ng technique can be utilized to attain coherent control; the specific timing between the pulses can be used to achieve near-unity or near-zero values of the transfer of population for molecules that

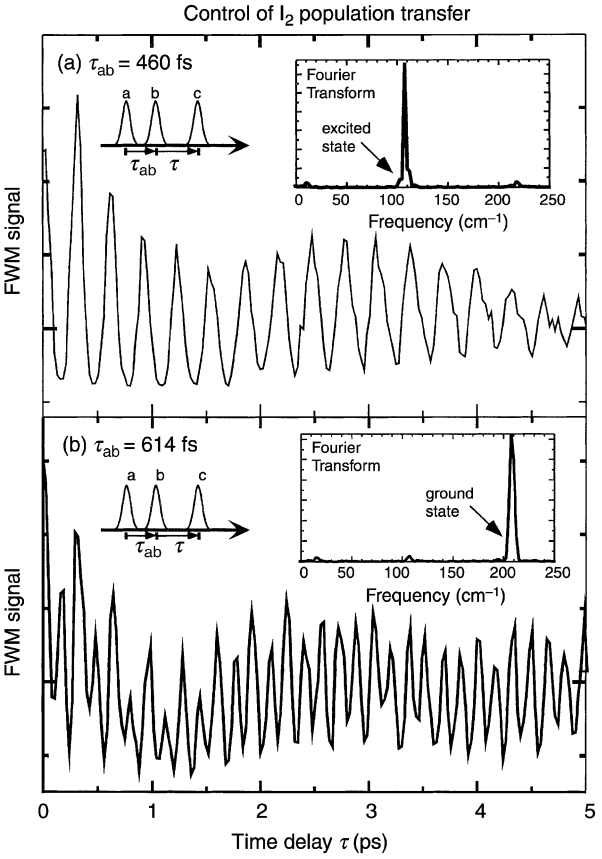

Figure 14 FWM signal in molecular iodine demonstrating control over observation of molecular dynamics. By using the pulse sequence shown, τ_{ab} was defined to be either (a) 460 fs or (b) 614 fs while τ was scanned in time. As is clearly evident in the data and the FFT, excited-state dynamics alone (307 fs oscillations) are observed with $\tau_{ab} = 460$ fs and ground-state dynamics (160 fs oscillations) are observed with $\tau_{ab} = 614$ fs.

interacted with the two electric fields. The Dantus group has also used three-pulse FWM to demonstrate control over optimizing the population transfer between two electronic states in iodine. The populations of the ground and excited states are controlled based on the time delay between the first two pulses τ_{ab} in the pulse sequence shown in Figure 6d. The transient is obtained as a function of the time delay between the second and third pulses, which probes the vibrational dynamics of the population; this experiment is illustrated in Figure 14. For Figure 14a using $\tau_{ab} = 460$ fs, only excited-state dynamics are observed; while for Figure 14b using $\tau_{ab} = 614$ fs, primarily ground-state dynamics are observed. This observation is confirmed by the Fourier transform of the time-resolved transient. The top transient has a vibrational frequency of 108 cm^{-1}, corresponding to the vibrational frequency of the excited B state. The bottom transient has a vibrational

frequency of 208 cm^{-1}, corresponding to the vibrational frequency of the ground state of iodine molecules.

Control Using Feedback and Evolutionary Algorithm

For complex molecules, one seldom knows the precise sequence of pulses or phase modulation of a given pulse that can optimize the yield of a chemical reaction. In these cases, a pulse-shaping device which manipulates the phase and amplitude of frequencies within an ultrashort pulse can be used. The device is part of a learning loop that includes a computer and an experimental setup. The learning algorithm running in the computer generates different pulses to be evaluated experimentally. Signal from the experiments is sent back to the computer for further refinement. The learning algorithm iteratively arrives at the optimum pulse. This method, first introduced by Rabitz, was first tested by Wilson. Gerber and co-workers have demonstrated automated control over the photodissociation reaction of organometallic compounds using an evolutionary algorithm with feedback. The organometallic compounds chosen were iron pentacarbonyl ($Fe(CO)_5$) and dicarbonylchloro(η^5-cyclopentadienyl)iron ($CpFe(CO)_2Cl$). For the first molecule, multiphoton absorption of femtosecond pulses at 800 nm caused ionization and fragmentation resulting in numerous ionic species – Fe^+, $Fe(CO)^+$, $Fe(CO)_2^+$, $Fe(CO)_3^+$, $Fe(CO)_4^+$, and $Fe(CO)_5^+$. These species were detected by mass spectrometry; the measured signal was used as feedback for the evolutionary algorithm that adjusts the phase of the femtosecond laser pulse. The $Fe^+$and $Fe(CO)_5^+$ exit channels were used to demonstrate the control available over branching ratios with this automated control method. Maximization (5.0) of the $Fe(CO)_5^+/Fe^+$ ratio was achieved with very short laser pulses while minimization (0.057) of this ratio was achieved with long (ps) pulses. These results were found to correspond well to changing the pulse duration of bandwidth-limited pulses. The optimization procedure did not attempt to control the other ionic species. This same automated optimization procedure was used to control the branching ratio of $CpFeCOCl^+/FeCl^+$ for the second organometallic compound. The maximum branching ratio was 4.9; the minimum was 1.2; and bandwidth-limited pulses yielded 2.4. Unlike the simpler carbonyl compound, simple changes to the pulse duration of a laser pulse could not optimize this branching ratio. The evolutionary algorithm with the feedback from the mass spectrometer allowed for these tailored pulses to be obtained and optimized the desired exit channel without any knowledge of the specific molecular system. The full potential of shaped femtosecond pulses has yet to be realized. It is possible that shaped femtosecond pulses will play an important role in future time-resolved experiments where they will be used to improve time resolution or to access potential energies that could not be reached with simpler pulses. Pulse shapers will also play a role in the preparation of ultrashort pulses with single femtosecond or attosecond duration.

List of Units and Nomenclature

Å	angstrom (10^{10} Å = 1 meter)
Attosecond	10^{18} as = 1 second
B	rotational constant
cm^{-1}	wavenumbers
D	centrifugal distortion constant
electron volts	1 eV = 8065 cm^{-1}
fs	femtosecond (10^{15} fs = 1 second)
FTS	femtosecond transition state spectroscopy
FWM	four-wave mixing
k	wavevector
LIF	laser-induced fluorescence
nm	nanometer (10^9 nm = 1 meter)
ps	picosecond (10^{12} ps = 1 second)
R(Å)	internuclear distance (given in angstroms)
$t = 0$	initiation of reaction (pump and probe are overlapped in time)
τ	time delay between pump and probe pulses being applied
TG	transient grating
ω_j	rotational frequency

Ultrafast Chemistry

Chemistry means rearrangement of atoms in/between molecules. Chemical bonds are broken and/or formed, leading to a change in chemical composition, from reactants to products, during a reaction. Following the temporal behavior of the reaction all the way from reactant – via possible intermediates – towards the product state(s), amounts to deciphering the molecular processes that lead to these chemical reaction dynamics. Molecular rearrangements from reactant to product may encompass many orders of magnitude in time (see **Figure 1**). Typically the larger and more involved the rearrangements are, the more time it takes for a molecular species to reach the final state. Rearrangements of biomolecular structure occur in micro- to milliseconds (spontaneous folding of small proteins consisting of several hundreds of amino acid units), or longer (DNA multiplication, protein synthesis in ribosomes). In these conformational dynamics, hundreds to thousands of chemical bonds change their nature. Bimolecular reaction dynamics in liquid solution occur on time-scales of nanoseconds or longer, being controlled by the relatively slow diffusional motions of the reaction partners to each other. Many elementary processes in chemistry, however, occur on much faster time-scales. In fact, when one considers the dynamical event of a single-bond rearrangement, the relocation of the (relatively few) atoms appears to take place as an ultrafast event. Bond fission, hydrogen and proton transfer, electron transfer, and cis/trans-isomerizations have been found to occur on femto- to picosecond time-scales ('femtochemistry'). The dynamics of these elementary processes are not only determined by the energy landscapes of the reacting partners. The energy landscapes (potential energy surfaces) are determined by molecular parameters such as relative orientation (distances, angles) of the reaction partners, the energy levels of the reactant, intermediate and product species, and – very important – the energy barriers represented by transition states. When considering condensed phase reaction dynamics, the important role of the surrounding solvent has been recognized. The solvent shells modulate energy levels of the reactant, intermediate and product states, through electrostatic interactions. In the liquid phase the solvent fluctuations lead through these interactions to fluctuating energy levels of the reaction partners. In addition, the solvent may facilitate chemical reactions through energy exchange with the reaction partners, leading to efficient dissipation of excess energy, making chemical reactions often irreversible. The processes that are extremely dominated by these solvent interactions (such as molecular collisions, electronic and vibrational dephasing, vibrational relaxation) are also often found to occur on femto- to picosecond time-scales. The outcome of a bond fission may be a null effect, when the dissociating fragments are forced by the surrounding solvent to recombine and relax ('cage effect').

Spectroscopy has been a prime tool to obtain insight into these key molecular processes. Reactant, intermediate, and products contribute to the spectra with their respective molecular resonances. With spectral domain spectroscopy one may, in principle, obtain a precise determination of structural information. Fluctuations of energy levels of these species by the solvent interactions, and finite lifetimes, contribute to a broadening of these molecular resonances. Using steady-state spectroscopy one

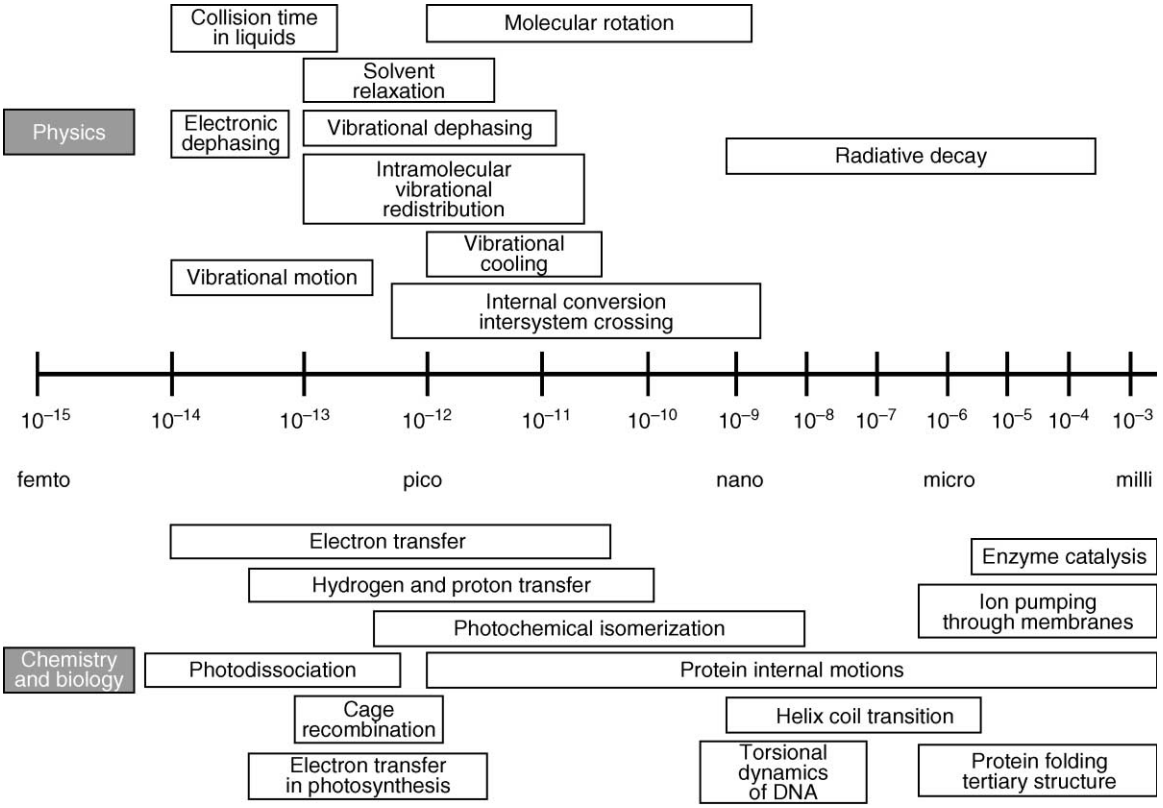

Figure 1 Chart showing the ultrafast time-scales of fundamental physical and chemical processes (inspired by charts of Fleming GR (1986) *Chemical Applications of Ultrafast Spectroscopy*. Oxford, UK: Clarendon Press and Zewail AH (2000) Femtochemistry: atomic-scale dynamics of the chemical bond. Nobel lecture as appeared in *Journal of Physical Chemistry A* 104(24): 5660–5694).

could try to determine these effects through a lineshape analysis. Using this approach, the results have to be analyzed with an a priori defined model representing the dynamics. The disadvantage lies in the averaging over all time-scales inherent in spectral domain spectroscopy, where details of transient states may be lost in this averaging procedure. In contrast, in experiments designed to grasp the molecular dynamics in real time, the temporal resolution is the prerequisite quantity in observation of these processes. In time-resolved experiments one can trigger a chemical reaction at a well-defined point in time, after which one can follow the conformational changes from reactant – via possible intermediates – to the product, and identify any possible transition states along the reaction pathways.

During the last century the technological advances in time-resolved spectroscopy have prompted significant breakthroughs in the study of chemical reaction dynamics. Initially the temporal resolution was given by the duration of flashes from light bulbs ('flash' spectroscopy) or by rapid mixing of reaction partners (stopped-flow technique), as developed by Nobel Laureates Eigen, Norrish, and Porter, and many others. These techniques allow a temporal resolution of at best milliseconds. Already, up to the early 1960s, it was understood that elementary reaction dynamics occur on much faster time-scales. Fourier spectroscopy may improve time resolution down to microseconds or slightly less. With the advent of pulsed laser sources with ever-increasing temporal resolution, a wide arena of time-resolved spectroscopic techniques has emerged. Nanosecond laser systems are known since the early 1960s, picosecond pulses can be generated since the 1970s, the first femtosecond laser system was reported in 1981, and currently laser engineering groups are breaking into the attosecond domain. The majority of pulsed laser systems operate at visible and near-infrared wavelengths. This means that usually chemical events in ultrafast time-resolved spectroscopy are initiated by electronic excitation ('photochemistry'). Subsequent molecular rearrangements have then to be followed by probing the electronic states through electronic resonances (UV/VIS pump–UV/VIS probe or UV/VIS four-wave mixing

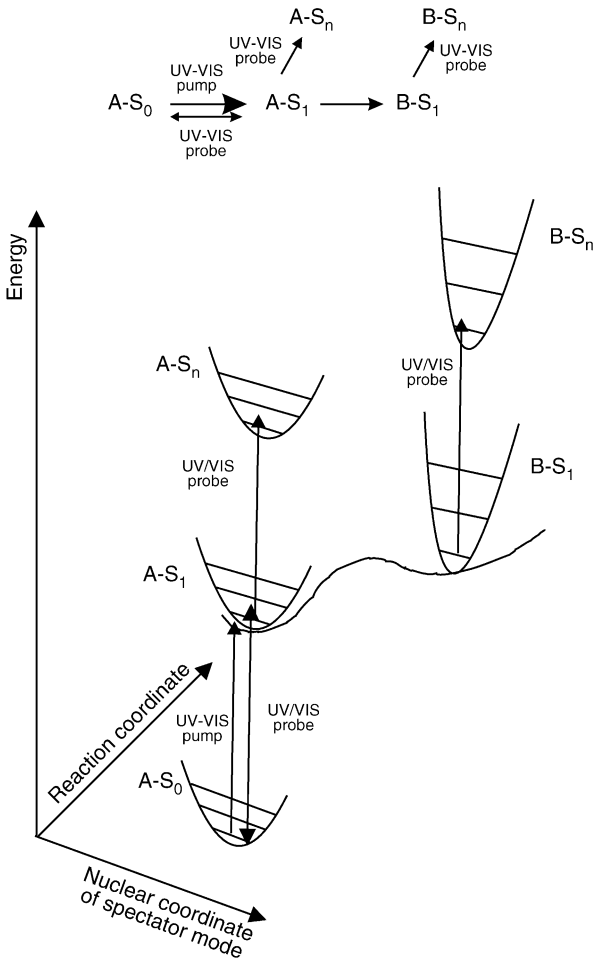

Figure 2 Ultrafast time-resolved electronic spectroscopy. A UV/VIS pump pulse excited an electronic resonance, and a probe pulse determines, depending on the tuning in the UV/VIS population changes in the reactant ground or excited states or in the product state.

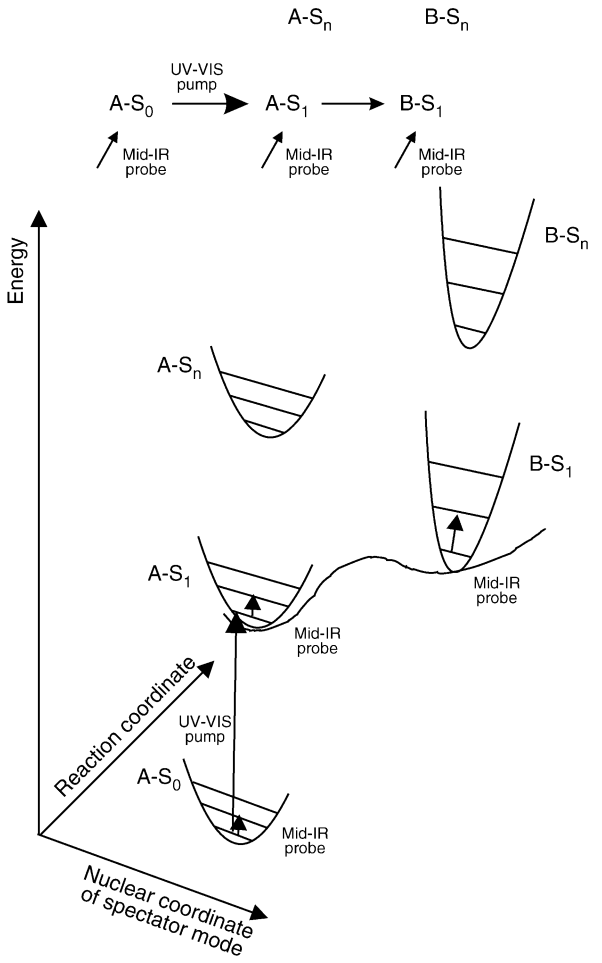

Figure 3 Ultrafast time-resolved infrared spectroscopy. A UV/VIS pump pulse excites an electronic resonance, after which the populations are followed with an infrared probe pulse by inspection of marker modes in the different electronic states.

spectroscopy) (Figure 2), or via vibrational resonances (UV/VIS pump–IR/Raman probe spectroscopy) (see Figures 3 and 4).

Laser Technology

Since the beginning of the 1990s, a major advancement in femtosecond laser technology has emerged by the discovery of Kerr lens mode locking in laser oscillators with Ti:sapphire as lasing material. Ultrastable and ultrashort laser pulses tunable between 700 and 1,000 nm can be generated with durations as short as 6 fs. The second advancement is due to the ability of Ti:sapphire as laser amplifying material, using the method of chirped pulse amplification. Pulses with output powers up to several W, with repetition rates in the kHz-regime, are now routinely generated. These developments facilitate the efficient generation of ultrashort pulses tunable from the UV to the mid-infrared, and even beyond to the THz-regime using schemes based on nonlinear optics. Frequency conversion of the fundamental output of an amplified Ti:sapphire laser system is then achieved with nonlinear processes such as self-phase modulation and supercontinuum generation, n^{th}-order harmonic generation ($n = 2, 3, 4,\ldots$), sum and difference frequency generation, or parametric generation and amplification. As a result, one can now almost arbitrarily tune the excitation and probe wavelengths of the applied laser pulses. Additional parameters, that one may alter, are pulse duration (from less than 10 fs up to several ps) and pulse energy (in the mJ range or less; typically one uses for

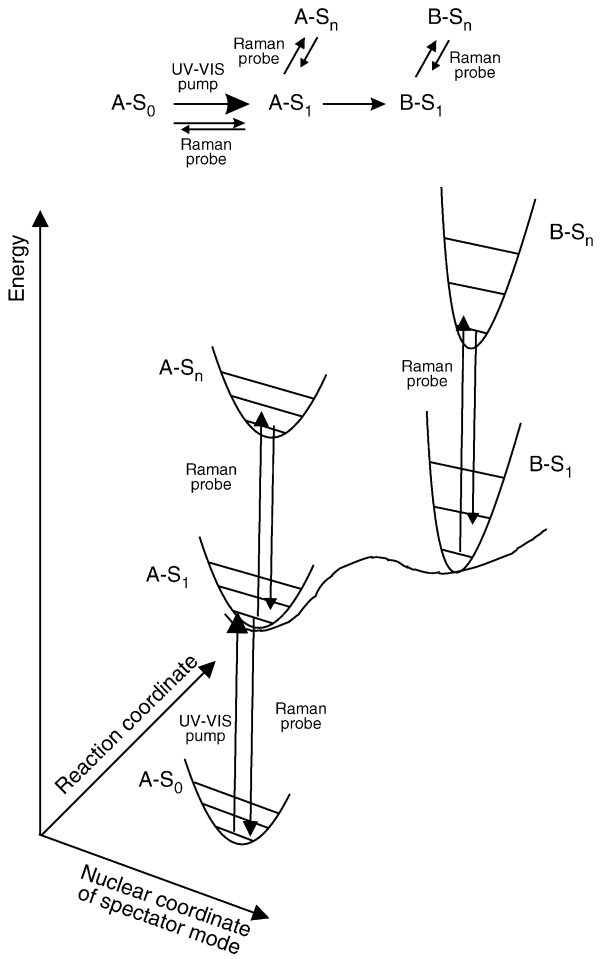

Figure 4 Ultrafast time-resolved Raman spectroscopy. A UV/VIS pump pulse excites an electronic resonance, after which the populations are followed with (resonance) Raman probe pulse by inspection of marker modes in the different electronic states.

condensed phase spectroscopy pulse energies in the range of nJ to μJ). More advanced pulse manipulation schemes use amplitude and phase masks. The latter aspect holds the promise of amplitude and phase control of molecular excitation, feeding the ultrafast chemist's dream of laser control of molecular reaction dynamics.

Ultrafast Electronic Spectroscopic Techniques

Pulsed laser sources enable a variety of experimental approaches to determine transient states. Already, since the development of nanosecond laser sources, time-resolved pump–probe and four-wave mixing spectroscopy have been widely used. In a first approach, often one uses these forms of spectroscopy to probe in real-time populations of reactant,

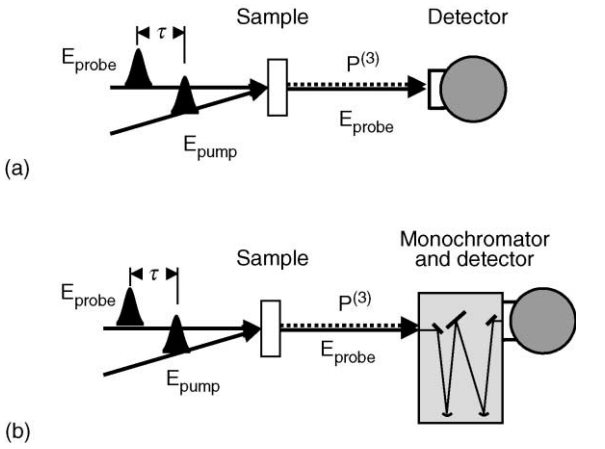

Figure 5 Pump–probe technique: A pump pulse induces an absorbance change in a sample, that is subsequently measured by a time delayed probe pulse, either spectrally integrated (a) or spectrally resolved (b).

transient, and product states as function of pulse delay. With the advent of pico- and femtosecond laser sources, coherence properties of the material response have been investigated as well.

The following techniques have been widely used in ultrafast electronic condensed phase spectroscopy.

UV/VIS Pump–UV/VIS Probe Spectroscopy

In this technique a 'pump' pulse resonant to a transition promotes the molecules to an electronic excited state, and the time-dependent populations are determined by measurement of the transmission of a time-delayed 'probe' pulse (Figure 5). The absorbance change $\Delta A(\tau) = -^{10}\log[T(\tau)/T(\tau = 0)]$ (with T for transmission change and τ the pulse delay) is a direct indication of populations of states. Here one can tune the probe pulse to the same transition as the pump pulse, and one measures an absorbance decrease due to a bleach of ground state population (i.e., fraction of molecules being excited), and due to molecules in the excited state stimulated back to the ground state. One could also tune the probe pulse to transitions between the transient state and higher lying states. For electronic spectroscopy, often transitions between the ground and first excited state ($S_0 \rightarrow S_1$) overlap with excited state absorptions ($S_1 \rightarrow S_n$). One has to rely then on numerical analysis procedures such as singular value decomposition and decay associated spectra, that correlate spectral features with temporal behavior.

The time resolution of the experiment is given by the cross-correlation between pump and probe pulses. In the case of extremely short pulses one has

to consider the effects of group velocity dispersion between different frequency components due to different travel times through the samples, leading to pulse temporal broadening. For the case of pump and probe tuned to different wavelengths, the time-resolution is usually dominated by group velocity mismatch between pump and probe pulses.

When ultrashort laser pulses are used, often the applied spectral bandwidth enables simultaneous excitation of several vibrational sublevels in vibronic transitions. Due to the phase-relationship of the applied laser pulses, these vibrational sublevels are prepared in states that are well-defined in temporal phase with respect to each other. Such a coherent superposition of vibrational eigenstates is nothing less than a vibrational wavepacket, that will evolve in time. The occurrence of vibrational wavepacket motions leads to oscillatory modulations of the pump–probe signals.

Time-Resolved Fluorescence Spectroscopy

Here again a 'pump' pulse excites an electronic resonance. The transient excited states are now probed through their spontaneous fluorescence emission, either by use of time-correlated single photon counting or by fluorescence upconversion with a gating pulse in a nonlinear medium (Figure 6). Single-photon counting has a time resolution of at best a few picoseconds. Fluorescence upconversion can be performed with a time resolution of 100–200 fs. The advantage lies in the fact that the measured signals are more likely due to the specific excited states only, and not corrupted by other contributions.

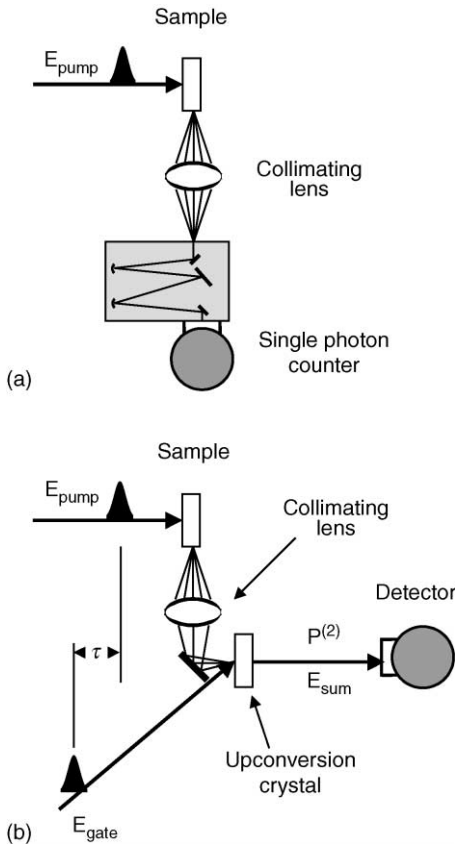

Figure 6 Time-resolved emission detection: The fluorescence emission is either temporally resolved by time-correlated single photon counting (a) or by up-conversion with a gating pulse (b).

Electronic Four-Wave Mixing Spectroscopy

In time-resolved degenerate electronic four-wave mixing spectroscopy, where all the three applied laser pulses (with wavevectors $\mathbf{k}_1$, $\mathbf{k}_2$, and $\mathbf{k}_3$) are tuned to the same electronic resonance, one can detect a nonlinear signal in the phase-matched direction $\mathbf{k}_S = \mathbf{k}_3 + \mathbf{k}_2 - \mathbf{k}_1$ (Figure 7). The first laser pulse generates a coherent superposition between the electronic ground and excited states. This electronic coherence evolves in time during the period (denoted as coherence time τ), until the second pulse converts this coherence in a population frequency grating in the electronic ground and excited states. After a second time period of free evolution (denoted as population or waiting time T), this frequency grating is again transformed into an electronic coherence, which after some time evolution generates a macroscopic polarization in the phase-matched directions. This macroscopic polarization is either directly measured by a time-integrating detector (in which case one measures the intensity signal proportional to the absolute square of the nonlinear polarization), or one uses another light pulse that mixes as local oscillator with the nonlinear polarization (and the signal is proportional to the amplitude of the polarization). The time resolution is determined by the third-order autocorrelation of the applied pulses.

Depending on the delay between the three input pulses, and which delay one varies, different dynamics can be measured. When one performs an experiment with τ scanned and T set at zero, one measures the electronic coherence decay (due to electronic dephasing) time in a two-pulse photon echo experiment. When, on the other hand, τ is set to zero, and T is scanned, one measures the evolution of a population grating, and electronic lifetimes can be deduced. In a three-pulse photon echo experiment both pulse delays are scanned, and the signals give insight into both electronic coherence and frequency grating decay (due to electronic dephasing and spectral diffusion, respectively). A novel extension of four-wave mixing technique is the three-pulse echo peak shift (3PEPS). In a 3PEPS measurement, the delay time τ_{max} is

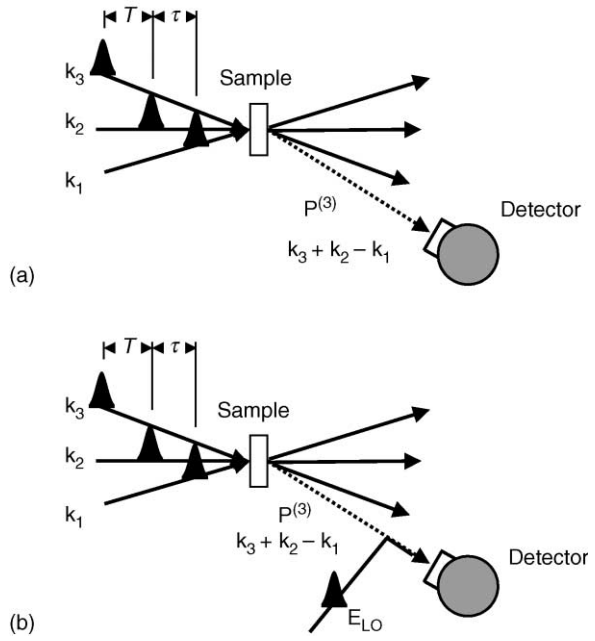

Figure 7 Beam geometry for time-resolved four-wave mixing (grating/photon echo) spectroscopy: The nonlinear signal is transmitted by the sample in a phase-matched direction and its intensity signal (a) or its amplitude by interference with a local oscillator field (b) is detected by a time-integrating detector.

determined, where the echo signal has a maximum along the coherence delay τ, as a function of the population delay T. This method provides direct insight into the frequency fluctuation correlation function that governs the linear and nonlinear signals. Extension of the method to multi-color four-wave mixing spectroscopy has been demonstrated.

Electronic Condensed Phase Spectroscopy: Femtochemistry and Solvation Dynamics

In the narrow sense of meaning, 'femtochemistry' deals with the real-time observation of nuclear motions during chemical reactions. Quantum mechanics teaches us that this is only possible when molecular systems are prepared in vibrational superpositions. Only in the case of quantum states describing vibrational wavepackets evolving in time the narrow-defined positions of nuclei allow for a real-time description of molecular rearrangements, or in other words: dynamics. This has been demonstrated in the gas-phase landmark experiments by Nobel Laureate Zewail (Figure 8).

In the condensed phase at room temperature, however, often such well-defined quantum states are hard to prepare, since the ensembles of molecular systems exist in mixed states. Coherent laser excitation on an ensemble will then prepare mixed states as well, and then information that one obtains from the experiments is less explicit. In addition, room temperature liquid solutions induce extremely fast fluctuations in the states of the molecules under study and as a consequence the electronic and vibrational coherences show ultrafast decaying behavior. This limits the temporal window with which one can follow the evolution of vibrational wavepackets.

Most of the ultrafast spectroscopic experimental work performed on photochemistry in the condensed phase, being described as 'femtochemistry', only deals with the time-scales of changes in electronic states (usually indicated with reaction rates typified with exponentially decaying or rising functions). In this regard it is better to speak of 'kinetics' rather than 'dynamics', although both terms are used in condensed phase spectroscopy. Due to the relative broad electronic spectra of condensed phase molecules masking any structural detail, it is hard to derive nuclear motions in real time, and as such it is difficult to make any statements about dynamics of molecular structures during chemical reactions.

Electronic resonances have also been used to probe the dynamical interactions between a nonreactive solute and the surrounding fluctuating solvent. The idea behind these experiments is to achieve information about the time-scales of solvent fluctuations on (and solvent motions due to a change in) the electronic charge distribution in a molecule (as induced by an electronic excitation). Usually the solvent motions are characterized with a frequency fluctuation correlation function (Figure 9). This information is highly relevant for the case of reacting molecules, where electronic motions accompany the relocations of nuclei, even in electron transfer reactions, where the nucleic rearrangements are modest. Solvent motions have been shown to often control reaction rates. Solvent rearrangement, as a response to a change in electronic charge distribution, is known as solvation dynamics. Experimental probes for solvent motional fluctuations are electronic coherence decay (electronic dephasing) and population frequency grating decay (spectral diffusion) that can be measured in two- and three-pulse photon echoes. Solvent adaptation to new charge distributions can be followed with the time-dependent Stokes-shift in fluorescence emission, as well as in three-pulse photon echoes (in so-called three-pulse echo peak shift measurements described above). Ultimately these experiments resolve the temporal characteristics of the frequency fluctuation correlation function.

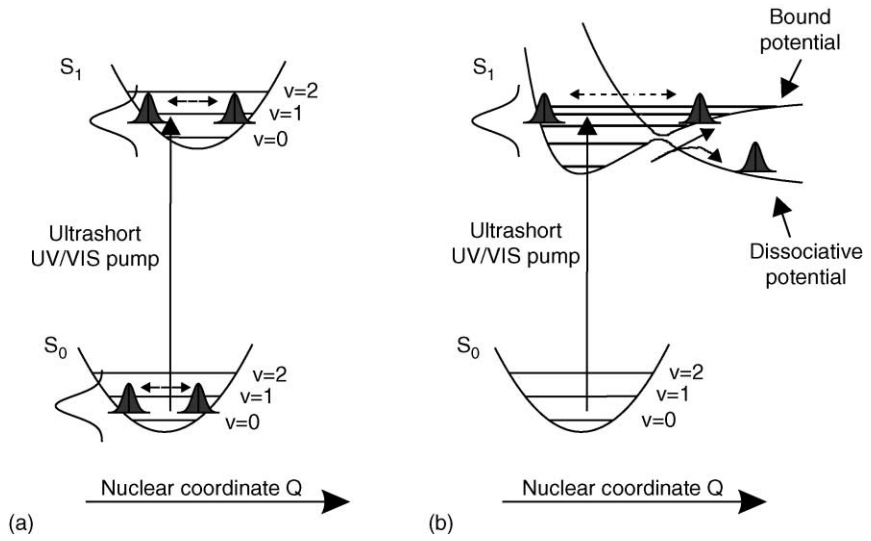

Figure 8 Ultrafast excitation with broadband pulses creates coherent superpositions of vibrational eigenstates, i.e., vibrational wavepackets. These wavepackets are generated in electronic excited and ground states (a), and their time-dependence can be determined in pump–probe and four-wave mixing experiments. When level crossing occurs to another electronic state, the vibrational wavepacket may be observed to evolve along the reaction coordinate (b).

Ultrafast Vibrational Spectroscopy in Photochemistry: Structural Dynamics

Vibrational spectroscopy has, despite a smaller signal sensitivity due to smaller transition cross-sections, several advantages over electronic spectroscopy. Vibrational transitions have typically smaller bandwidths than electronic transitions, due to longer dephasing times (the exception to the rule: O–H/O–D stretching bands of hydrogen bonded hydroxyl groups). Specific signal contributions are thus easier tractable in vibrational spectroscopy than in electronic spectroscopy. Vibrational bands can often be correlated to specific vibrational motions by inspection of the transition frequencies, (e.g., O–H, N–H, and C–H stretching bands can be found in the 3000 cm^{-1} range, C=O and C=N stretching modes are located near 1,600–1,750 cm^{-1}, O–H, N–H, and C–H bending vibrations between 1,500–1,650 cm^{-1}, C–O stretching mode around 1,200–1,300 cm^{-1} etc.), and, in particular, the frequency range between 1,000 and 1,800 cm^{-1} is called the fingerprint region because of this reason. Measurement of vibrational bands thus leads to identification of particular vibrational motions, and conclusions can be drawn on specific structural motifs in the molecules. Vibrational bands can be infrared (IR) or Raman active, sometimes both, and both IR and Raman techniques have been widely applied in structural determination studies ranging from small molecules to larger biomolecular systems. In ultrafast photochemistry one thus excites the molecules with a UV/VIS pump pulse, and an IR/Raman probe pulse follows the outcome of the chemical reaction by inspection of vibrational bands of reactant, transients, and products.

Vibrational spectroscopy has the potential of revealing site-specific information if the marker modes are due to nuclear motions of specific molecular side-groups. For instance, hydrogen bonding induces marked shifts of O–H, N–H, C=O, and C=N bands. Observation of changes in spectral shifts reveals important information on hydrogen bond interactions (weakening/strengthening or even hydrogen bond cleavage). Infrared spectroscopy is able to probe small molecular species in solution that typically have their electronic resonances in the far-UV (making electronic spectroscopy impossible, since normally the solvent would absorb this radiation) (Figure 10). For instance, in acid–base neutralization reactions, where the acidity of a so-called photoacid is switched on by use of a UV pulse, a VIS probe pulse would only be able to probe the photoacid (or its conjugate photobase), thus revealing only when a proton leaves the photoacid. An infrared pulse can, besides probing vibrational resonances of the photoacid, also probe bands of a small base (or its conjugated acid) indicating when a proton arrives at the base.

In the case where the vibrational normal modes do not allow such a structural insight into site-specific groups, one can make a comparison of the

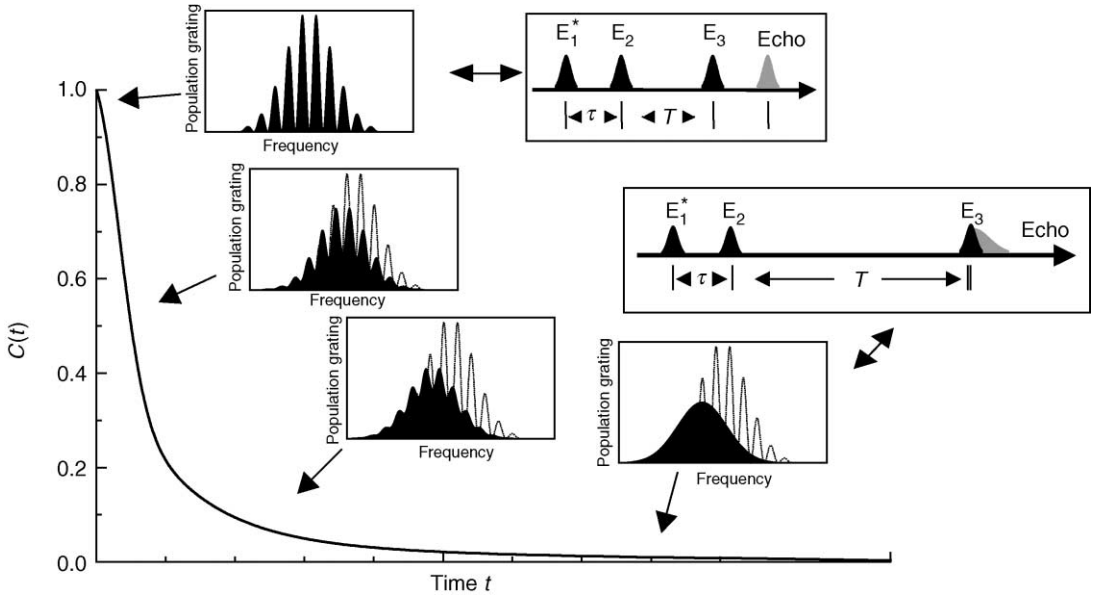

Figure 9 Solute–solvent interactions as characterized by the transition frequency fluctuation correlation function $C(t)$. This quantity can be measured in photon echo and time-resolved fluorescence experiments. In a three-pulse photon echo experiment phase information as given by the excited state frequency grating created with the first two interactions, is washed out due to solvent fluctuations and Stokes shifts to lower frequencies due to solvent rearrangement. A similar plot can be drawn for the ground state frequency grating.

experimentally observed vibrational bands with predictions made by quantum chemical calculations. When a full correspondence between experiment and theory is possible, one can make statements about the three-dimensional structure. With current quantum chemical calculational routines, such as density functional theory, medium-sized molecules are routinely calculated for electronic ground-state conformations. Reliable results of transient and product states in electronic excited states can be obtained with the routine *ab initio* complete active space self-consistent field (CASSCF), albeit for mid-size molecules of at most on the order of about 20 atoms. New developments in numerical procedures, such as time-dependent density functional theory (TD-DFT) may prove fruitful in the calculation of larger molecular systems in electronic excited states.

During recent years, femtosecond IR spectroscopy has been used in photo-induced chemical reactions ranging from excited state hydrogen and proton transfer, transformations of photochromic switches, excited state charge transfer, and cis–trans isomerizations. Here an ultrashort UV/VIS 'pump' pulse promotes the molecule to an electronic excited state, and the reaction is followed by a measurement of the absorbance change of a 'probe' pulse tuned in the mid-IR region where the vibrational marker modes sensitive to structural changes have their resonances. Experimentally, one performs spectrally resolved transient IR spectroscopy. Femtosecond IR parametric devices deliver pulses with bandwidths of 150 cm^{-1} or more. In order to be able to observe shifts as small as the linewidths of IR-active vibrations, one usually measures the IR absorbance change with a detector after spectral dispersion with a monochromator. As a side-effect of this spectral dispersion ground-state bleach signals often appear to grow in at negative pulse delay with the dephasing time of the transition. This effect, known as 'perturbed free induction decay' is a common feature of spectrally resolved nonlinear pump–probe spectroscopy of bleached transitions with dephasing times much longer than the time resolution of the experiment. The time resolution of the experiment is given by the cross-correlation between the UV/VIS-pump and IR-probe pulse (about 100–200 fs), and is typically dominated by group velocity mismatch in samples with thicknesses of about 100 μm.

In principle, the same approach can be followed by probing Raman-active vibrations. In this case the spectral resolution is not only determined by the monochromator through which the spontaneous Raman emission dispersed, but also by the bandwidth of the gating pulse by which the Raman effect is induced. As a result, UV/VIS pump–Raman probe

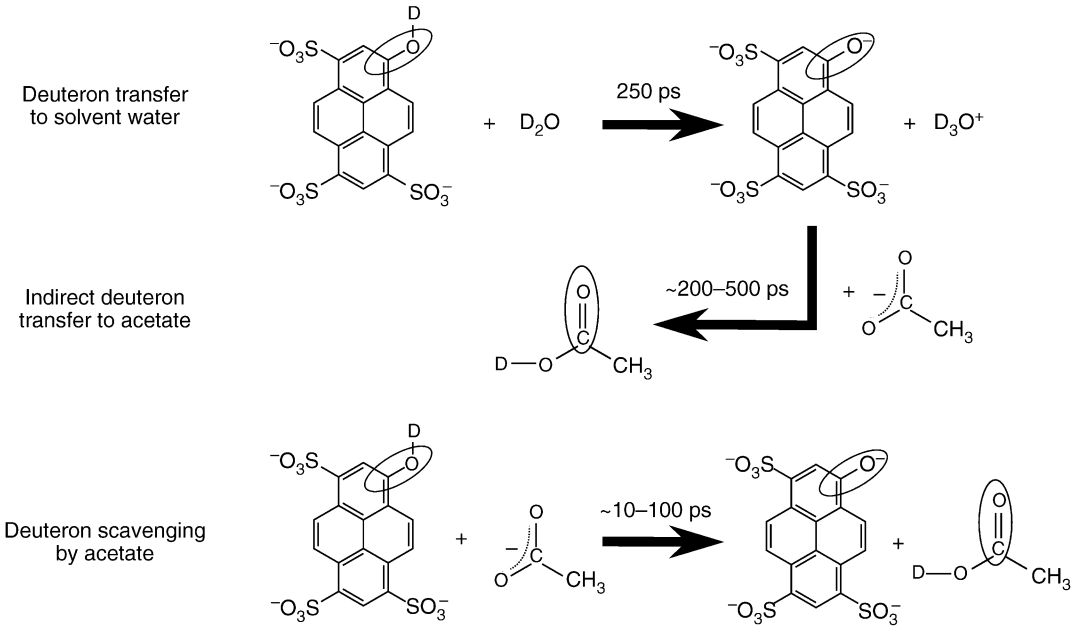

Figure 10 In excited state acid–base neutralization experiments, the proton dissociation can be followed on two sides with ultrafast infrared spectroscopy. Vibrational marker modes of photoacid and conjugated photobase indicate when the proton leaves the acid. The marker mode of acid formed by proton pick-up by the accepting base is a direct measure of the arrival time of the proton at the base. Depending on relative concentrations, either the indirect proton transfer via the solvent or direct scavenging of the proton by the base dominates the dynamics.

spectroscopy has a temporal resolution of around 1 ps (a compromise between spectral and time resolution). Due to the even weaker cross-sections of Raman transitions, one often uses resonance enhancement by tuning the gating pulse close to or resonant with an electronic transition of the state that is probed. The advantage is that one usually only observes Raman bands of the state under inspection. The drawback is that fluorescence resulting from the resonant electronic excitation often inhibits detection of Raman bands in extended spectral ranges.

Raman spectroscopy offers an additional insight into how chemical reactions evolve. By comparison of the intensities of anti-Stokes and Stokes lines of a particular vibration, it is possible to derive time-dependent changes in the excitation level of this vibration. One can draw conclusions on whether particular modes initially drive a chemical reaction ('state transition promoting modes'), or only get excited after the transition is made, by taking up the excess energy released by the reaction ('accepting modes'). In such a way, insight is obtained on the energy flow inside a molecular system (intramolecular vibrational redistribution, abbreviated as IVR) and vibrational energy dissipation to the surrounding solvent (vibrational cooling). Infrared spectroscopy is less powerful in revealing this, since red-shifted transient absorption of vibrational bands may either mean that the particular mode is highly excited (the red-shift is a consequence of the diagonal anharmonicity of the vibration), or it may mean that other modes are highly excited and these cause a red-shift of the marker mode under inspection (the red-shift is then due to off-diagonal anharmonic coupling with other modes).

Equilibrium Structural Dynamics in the Electronic Ground State

Existence of anharmonic coupling between vibrational modes means that the vibrational motions are not decoupled from each other. These couplings always exist, since otherwise no IVR and vibrational cooling (no relaxation) would occur. When the couplings are significantly large, excitation of one specific mode will induce a significant instantaneous shift of other vibrations anharmonically coupled to this particular mode. Estimation of the magnitude of these couplings should lead to a determination of the curvatures of potential energy surfaces along the respective coordinates. With current state-of-the-art femtosecond infrared technology (with time resolution of about 150 fs or less) it is possible to excite

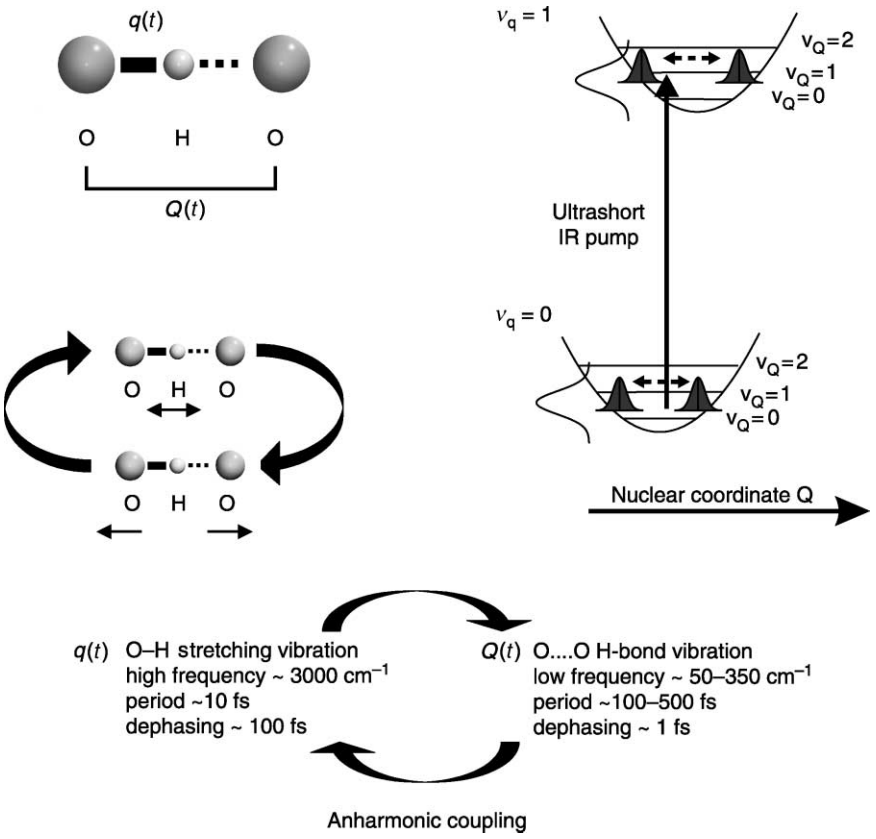

Figure 11 In hydrogen-bonded hydroxyl groups a strong anharmonic coupling exists between the hydroxyl stretching and modes modulating the hydrogen-bond distance. A Born–Oppenheimer-like separation of time-scales of vibrational motion between the high-frequency O–H/O–D stretching and the low-frequency hydrogen bond modes enables a description with potential energy surfaces for the low-frequency mode as a function of the quantum state of the hydroxyl stretching vibration. The formation of low-frequency vibrational wavepackets in ultrafast IR spectroscopy of O–H/O–D stretching modes is then fully analogous to wavepacket formation in ultrafast electronic spectroscopy.

infrared-active vibrations and to probe the same or other vibrations (either in the IR or by the Raman process), enabling insight into the anharmonic couplings between these vibrational modes.

Direct anharmonic couplings are probed in IR-pump–IR-probe and IR photon echo spectroscopy (Figure 11). In the case of peptides, the excitonic (Davydov) couplings between amide I vibrations of the amino acid units have been the subject of extensive study since these lead to spatial information of the relative orientations of the different amide I modes, and thus, of the spatial orientation of the amino acid units inside the peptide. Exploring the effects of the delay between the IR pulses on the observed signals, give insight into the fluctuations of these orientational features, or in other words, into structural dynamics of peptides. In the case of hydrogen bonded O–H/O–D stretching vibrations, the anharmonic couplings with under-damped low-frequency modes modulating the hydrogen bond distance, lead to marked modulations of observed pump–probe and echo signals as function of pulse delay. These experiments reveal which modes couple strongly to the hydrogen stretching oscillator.

Fluctuations in couplings between vibrational modes (in particular with those of the solvent) induce dephasing of the vibrational coherences. The dephasing and spectral diffusion dynamics of vibrational transitions, e.g., the O–H stretch vibration of HOD dissolved in D_2O, have been determined by IR photon echo spectroscopy. From these studies the time-scales of structural memory decay of hydrogen bond networks can be derived. Couplings between vibrational modes ultimately lead to population relaxation through intramolecular vibrational redistribution effects and vibrational cooling. Ultrafast two-color IR-pump–IR-probe reveals whether excitation of one IR-active vibration is followed by population transfer into another IR-active mode.

With IR-pump–Raman-probe, one can estimate whether Raman-active vibrations are transiently excited. In the case of hydrogen-bonded O–H/O–D stretching bands, an extremely short population relaxation time T_1 (below 1 ps) is observed, as well as an ultrarapid dephasing time T_2 (200 fs or less). These values are definitely longer for other vibrations, from which it has been concluded that the strong anharmonicities in hydrogen-bonded vibrational systems enable dephasing and relaxation processes to have such a rapid impact.

Future Developments

Future activities in the determination of dynamically evolving molecular structures in the condensed phase, may involve the aforementioned application of amplitude and phase controlled excitation pulses in optimal control of chemical reactions. Vibrational spectroscopy may be used as a tool in determination of evolving structures after electronic excitation by a shaped pulse tuned in the UV/VIS. Infrared pulses could also be shaped in amplitude and phase, and may be used in the exploration of steering of chemical reactions in the electronic ground state. Multidimensional vibrational spectroscopy is an object of extensive research. Extension of the method to determination of structure of transient states will lead to new results on molecular rearrangements, e.g., polypeptides reaching a new equilibrium after inducing a UV-excitation induced geometric change of a photochromic switch incorporated in the peptide structure. Much activity is currently also being put in the development of ultrafast structure resolving techniques such as electron diffraction, X-ray diffraction, and X-ray spectroscopy. While still extremely demanding at a technological level, final implementation of these latter techniques will open up new areas of ultrafast chemical dynamics.

Introduction

Mode-locked lasers emitting ultrashort pulses have expanded the range of available instruments and techniques to the scientific community. The unique properties of these ultrashort pulses – their high peak powers and short duration – enable such diverse applications as multiphoton microscopy, pump-probe experiments, and coherent control of molecular and atomic wavepackets, to name a few. Ultrashort pulses can also be used as a basis for ultrahigh data rate optical communications using time division multiplexing (TDM) in a fiber communication application. These ultrafast applications often require complementary real-time optical processors based on instantaneous nonlinear phenomena, since conventional electronic means are limited by the response time of electronic devices.

During the last few years, we have developed real-time optical processors utilizing nonlinear three- and four-wave mixing of signals originating from spatial or temporal channels for synthesizing, processing, and detecting ultrafast waveforms. We perform real-time optical signal processing that can be applied to data conversion between slow parallel channels in space and an ultrafast serial signal. A time-to-space mapping processor has been built for detection of ultrafast waveforms. It mixes two spatially inverted temporal frequency information waves in a three-wave mixing arrangement, generating a quasi-monochromatic spatial signal carrying the temporal image for detection by slower electronic means. A space-to-time mapping processor was constructed for generation of arbitrary ultrafast waveforms from an input ultrashort pulse. The waveform is a time-scaled replica of the employed input spatial image, converted by a four-wave mixing arrangement. By introducing only temporal information channels to our four-wave mixing processors, real-time optical processing of temporal waveforms was enabled. We have demonstrated time reversal experiments based on performing spectral phase conjugation and spectral inversion operations, achieving time reversal of the electrical field and of the complex amplitude waveform, respectively. The three- and four-wave mixing arrangements are performed within a spectral processing device – a free-space optical setup consisting of diffraction gratings and lenses – utilizing a $\chi^{(2)}$ nonlinear crystal. A cascaded second-order nonlinearity technique is used for four-wave mixing within the $\chi^{(2)}$ crystal (a frequency-sum generation process followed by a frequency-difference generation process satisfying the type-II noncollinear phase matching condition). However, a $\chi^{(3)}$ nonlinear crystal may be readily substituted without loss of generality (albeit with a likely smaller conversion efficiency).

This article reviews the spatial/temporal processing techniques for synthesizing, processing, and detecting ultrafast waveforms. The generation of spectrally decomposed waves within a spectral processing device is described in the following section. The subsequent section articulates on the employed nonlinear wave mixing processes, and the ensuing sections express the synthesis, processing, and detection of ultrafast waveforms.

Generation and Characteristics of Spectrally Decomposed Waves

Our wave mixing experiments are performed with spectrally decomposed waves, in which the spectral frequency content is spatially dispersed. When the pulse is decomposed with high resolution, the signal at every spatial location can be treated as quasi-monochromatic. This allows for increased interaction length within a nonlinear crystal, allowing us to use long crystals, whereas typically the interaction length is limited by temporal walkoff. In this section we analyze the creation of spectrally decomposed waves.

We introduce an ultrashort optical waveform, with a temporal envelope of $s(t/\tau)$, into the spectral processing device, where τ parameterized the waveform's duration. The waveform is propagating in free space towards a diffraction grating, at an incidence angle θ (see Figure 1). The input ultrashort waveform is characterized in its coordinate system (x_1, z_1) as:

$$E_{\text{pulse}}(x_1, z_1; t) = w\left(\frac{x_1}{L_1}\right) s\left(\frac{t - t_0 - z_1/c}{\tau}\right) \times \exp\left(\mathrm{i}\left(\omega_0 t - \frac{\omega_0}{c} z_1\right)\right) \qquad [1]$$

where $w(\cdot)$ defines the transversal field distribution with a scale size parameter L_1, t_0 is a time delay parameter, c is the speed of light in vacuum, and ω_0 is the center optical frequency. The waveform is

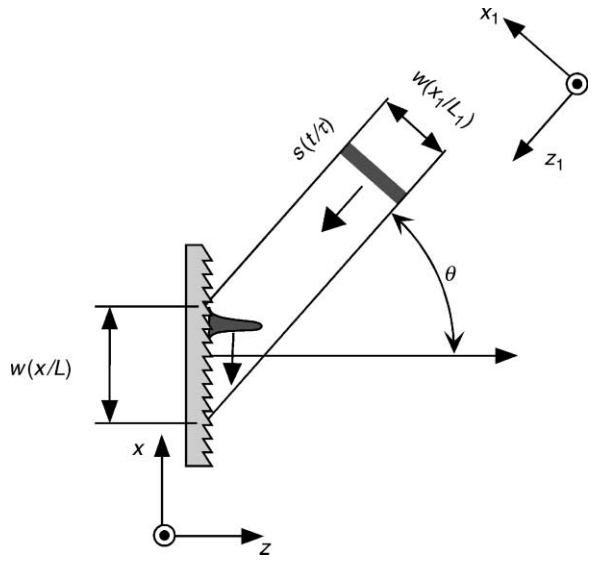

Figure 1 An ultrashort optical waveform, $s(t/\tau)$, propagating in free-space is incident upon a diffraction grating at angle θ. The transverse spatial mode of the pulse is stretched due to the projection onto the grating.

propagating in the z_1 direction at a group velocity and phase velocity of the speed of light in vacuum. The spatial confinement in the y_1 direction is omitted for brevity. We perform a time-domain Fourier transform (TFT) on eqn [1] to perform a frequency decomposition of the ultrafast waveform, yielding:

$$\tilde{E}_{\text{pulse}}(x_1, z_1; \omega) = \tau w\left(\frac{x_1}{L_1}\right) \times \exp\left(-\mathrm{i}\frac{\omega}{c} z_1\right) \tilde{s}(\tau(\omega - \omega_0)) \times \exp(-\mathrm{i}(\omega - \omega_0)t_0) \quad [2]$$

where the tilde over the script denotes a FT relationship, defined for the TFT as $\tilde{s}(\omega)A \int s(t)\exp(-\mathrm{i}\omega t)\mathrm{d}t$. Next we perform a rotation of the coordinate system from (x_1, z_1) to (x, z), for compatibility with the coordinate system of the spectral processing device, yielding:

$$\tilde{E}_{\text{pulse}}(x, z; \omega) = \tau w\left(\frac{x\cos\theta - z\sin\theta}{L_1}\right) \times \exp\left(-\mathrm{i}\frac{\omega}{c}(x\sin\theta + z\cos\theta)\right) \times \tilde{s}(\tau(\omega - \omega_0))\exp(-\mathrm{i}(\omega - \omega_0)t_0) \quad [3]$$

To find the incident field on the input grating of the spectral processing device, the field of eqn [3] is evaluated at $z = 0$. The effect of the grating diffraction can be modeled by adding the grating momentum, k_g, in the x direction to the k-vector that characterizes the propagation direction of the wave, resulting in:

$$\tilde{E}_{\text{input}}(x, 0; \omega) = \tau w\left(\frac{x\cos\theta}{L_1}\right) \times \exp\left(-\mathrm{i}\left(\frac{\omega}{c}\sin\theta - k_g\right)x\right) \times \tilde{s}(\tau(\omega - \omega_0))\exp(-\mathrm{i}(\omega - \omega_0)t_0) \quad [4]$$

The grating momentum, k_g, and the incidence angle, θ, are chosen such that the center frequency ω_0 will diffract in the direction of the optical axis of the system. Setting $\omega_0/c \cdot \sin\theta = k_g$ and substituting the grating's k-vector, $k_g = 2\pi/\Lambda$, where Λ is the grating period, yields $\sin\theta = \lambda_0/\Lambda \equiv \alpha$, where λ_0 is the optical wavelength corresponding to the center carrier frequency. To further simplify the notation, we define a new spatial width scaling parameter $L = L_1/\cos(\theta)$, accounting for the aperture size increase due to the projection onto the diffraction grating. With these substitutions, the expression takes on the more familiar form, given by

$$\tilde{E}_{\text{input}}(x; \omega) = \tau w\left(\frac{x}{L}\right)\exp\left(-\mathrm{i}\frac{(\omega - \omega_0)\alpha x}{c}\right) \times \tilde{s}(\tau(\omega - \omega_0))\exp(-\mathrm{i}(\omega - \omega_0)t_0) \quad [5]$$

We may perform an inverse TFT on eqn [5] to characterize the input signal in the time domain, yielding:

$$E_{\text{input}}(x; t) = w\left(\frac{x}{L}\right)s\left(\frac{t - t_0 - \alpha x/c}{\tau}\right)\exp(\mathrm{i}\omega_0 t) \quad [6]$$

Equation [6] describes the input waveform scanning across the fixed aperture at velocity of c/α in the x-direction.

The spectrally decomposed wave is generated by performing a spatial Fourier transform (SFT) employing a lens of focal length f on the input wave (either frequency domain representation, eqn [4], or time domain representation, eqn [6]). Using the frequency domain representation, the spectrally decomposed wave U_{SDW} of the input waveform is given by

$$U_{\text{SDW}}(x'; \omega) = \tau\tilde{s}(\tau(\omega - \omega_0)) \times \exp(-\mathrm{i}(\omega - \omega_0)t_0)\int_{-\infty}^{\infty} w\left(\frac{x}{L}\right) \times \exp\left(-\mathrm{i}(\omega - \omega_0)\frac{\alpha x}{c}\right) \times \exp\left(-\mathrm{i}2\pi\frac{xx'}{\lambda_0 f}\right)\mathrm{d}x \quad [7]$$

where we use the central wavelength in the Fourier transform kernel. Evaluating the integration of eqn [7], yields:

$$U_{\mathrm{SDW}}(x';\omega) = L\tau\tilde{s}\left(\tau(\omega-\omega_0)\right)\exp(-\mathrm{i}(\omega-\omega_0)t_0) \times \tilde{w}\left(\frac{\alpha L}{2\pi c}\left[\frac{\omega_0 x'}{\alpha f}+(\omega-\omega_0)\right]\right) \quad [8]$$

where the SFT of the input pupil function, $\tilde{w}(f_x)A\int w(x)\exp(-\mathrm{i}2\pi x f_x)\mathrm{d}x$, has mixed space-domain and time-domain frequency variables in its argument, characterizing the dispersion. A spectral component shifted away from the center frequency, $\Delta\omega = \omega - \omega_0$, will be centered at a displaced location $\Delta x' = -\Delta\omega\cdot\alpha f/\omega_0$, defining the spatial dispersion term $\partial x'/\partial\omega = -\alpha f/\omega_0$. One can see that in order to get fine localization of each spectral component, the spatial extent of the function $\tilde{w}(\cdot)$ must be minimized. This can be readily achieved by increasing the size of the input aperture, or the parameter L, as well as increasing α (grating's angular dispersion). Let us make the following observation on system resolution: The ultrafast pulse's spectral width is proportional to $1/\tau$, and its spatial extent is therefore proportional to $\alpha f/\omega_0\tau$ (multiplying by the spatial dispersion term). The spatial width of each spectral component is proportional to $cf/\omega_0\tau$. The dimensionless ratio of these two spatial widths, which is indicative of the number of resolvable spectral components, is $N \sim \alpha L/c\tau$, where N is defined as the system spectral resolution. When the spectral processing device is designed to satisfy the requirement of $N \gg 1$, then the spectrally decomposed wave can be considered quasi-monochromatic at every spatial position. In our experiments, we use $\lambda_0 = 800$ nm, gratings of 600 lines/mm frequency ($\Lambda = 1666$ nm), $L \approx 1$ cm, and $\tau \approx 100$ femtoseconds, yielding $\alpha \cong 0.5$ and $N \sim 160$, easily satisfying the high spectral resolution requirement. Let us make a second observation on system resolution using the time domain representation of eqn [6]: The spatial extent of the input aperture is proportional to L, whereas the instantaneous spatial extent of the scanning waveform is proportional to $\tau c/\alpha$ (see **Figure 2**). The dimensionless ratio of these two spatial widths is again $N \sim \alpha L/c\tau$, exemplifying the concept of resolvable positions and demonstrating the conservation of the space-bandwidth product.

To further facilitate the ensuing analysis, let us assume that we operate in the high-resolution regime (satisfied with the values given above), and we seek to simplify the expressions defining the spectrally decomposed wave. The spectrally decomposed wave

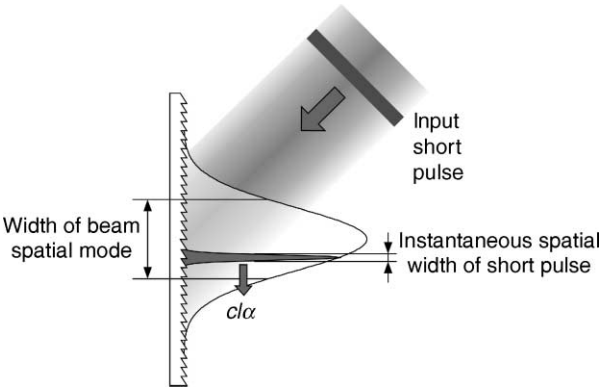

Figure 2 The input short pulse scans across the diffraction grating at velocity of c/α. The ratio of the width of the spatial mode of the beam to the instantaneous spatial width of the scanning waveform determines the system resolution. © 2001 Optical Society of America.

can be defined in the time domain by performing a SFT on eqn [6], yielding:

$$\begin{aligned} U_{\mathrm{SDW}}(x';t) &= \int w\left(\frac{x}{L}\right)s\left(\frac{t-t_0-\alpha x/c}{\tau}\right)\exp(\mathrm{i}\omega_0 t) \times \exp\left(-\mathrm{i}\frac{2\pi}{\lambda_0 f}xx'\right)\mathrm{d}x \\ &\approx w\left(\frac{c(t-t_0)}{\alpha L}\right)\exp\left(-\mathrm{i}\frac{\omega_0(t-t_0)x'}{\alpha f}\right) \times \tilde{s}\left(-\frac{\omega_0\tau x'}{\alpha f}\right)\exp(\mathrm{i}\omega_0 t) \end{aligned} \quad [9]$$

where by account of the high-resolution approximation, the instantaneous location of the traveling signal waveform samples the value of the aperture function and removes the aperture dependence from the Fourier integral. This approximation decouples the aperture function from the temporal waveform, and illustrates that the duration of the spectrally decomposed wave is defined by the aperture function (time of flight through aperture of size L), and that the spatial dependence is a mapping of the incident waveform spectrum. A rotating wavevector in time is also present, on account of the traveling (moving) waveform on the input plane. Again, we may perform a TFT on eqn [9], defining the high-resolution limit of the spectrally decomposed wave, yielding:

$$U_{\mathrm{SDW}}(x';\omega) = \tilde{s}\left(-\frac{\omega_0\tau x'}{\alpha f}\right)\exp(-\mathrm{i}(\omega-\omega_0)t_0) \times \tilde{w}\left(\frac{\alpha L}{2\pi c}\left[\frac{\omega_0 x'}{\alpha f}+(\omega-\omega_0)\right]\right) \quad [10]$$

One can compare eqns [8] and [10], as both characterize the spectrally decomposed wave in the

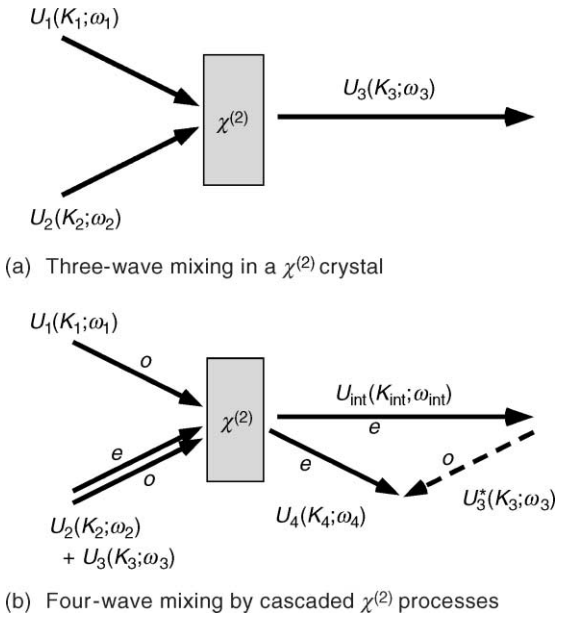

Figure 3 (a) Three-wave mixing interaction: two input waves U_1 and U_2, generate a third wave U_3. (b) Four-wave mixing by cascaded second order nonlinearities: three input waves, U_1, U_2, and U_3, generate a fourth wave U_4. The first two waves generate an intermediate wave U_{int}, by a frequency-sum process, followed by a frequency-difference process between the intermediate wave and the third input wave.

temporal frequency domain, and observe that the difference lies with the argument of the spectral term. If we apply the high-resolution approximation to eqn [8], then each spectral component would occupy a small region in space, as defined by the extent of the aperture function's SFT. Substituting for $\omega - \omega_0$ by $-\omega_0 x'/\alpha f$ for the spectral argument of eqn [8], corresponding to the high-resolution limit, equates the two expressions (essentially the same approximation as was performed in deriving eqn [9]).

Nonlinear Wave Mixing With Nondepleting Pumps

A nonlinear crystal exhibiting a large nonlinear susceptibility $\chi^{(2)}$ is placed at the Fourier plane of the spectral processing device. We employ noncollinear phase matching in our experiments. Either type-I or type-II phase matching conditions can be used in three-wave mixing experiments, with the resultant frequency-sum wave propagating along the bi-sector direction (see Figure 3a). Since both input waveforms are at ω_0 frequency, the generated field will be at a doubled carrier frequency, $2\omega_0$, due to the frequency-sum process. Four-wave mixing experiments use type-II phase matching in the $\chi^{(2)}$ crystal, involving a frequency-sum process generating an intermediate wave followed by a frequency-difference process between the intermediate wave and the third input wave. The resultant wave will copropagate with one of the input waves and at the same temporal carrier frequency (propagation direction and frequency ω_0), albeit at an orthogonal polarization state (see Figure 3b). The output signal can be extracted using a polarizer or a polarizing beam splitter. The interacting input waves propagate noncollinearly at the Fourier transform plane by offsetting the signals from each other at the input plane of the spectral processing device.

While it is possible, though often difficult, to obtain a precise analytic solution to the coupled mode equations governing the wave-mixing processes for the generated waves, it is beyond the scope of this article whose focus is on the signal processing functionality. We therefore limit the analysis to weak interactions with nondepleting input waves. Using the nondepleted input waves approximation, the nonlinear polarization term, which drives the generation of new waves, is constant and an ordinary differential equation characterizes the generation process.

The nonlinear polarization for the frequency-sum process is proportional to the product of the input waves, when expressed in the time domain: $P_{NL}^{sum}(x';t) = \chi_{eff}^{(2)} U_1(x';t) U_2(x';t)$. The nonlinear polarization for the frequency-difference process is proportional to the product of an input waves and a conjugated input wave: $P_{NL}^{diff}(x';t) = \chi_{eff}^{(2)} U_1(x';t) U_2^*(x';t)$.

The solution of the ordinary differential equation driving the generation of the new wave, takes into account the possible phase mismatch between the propagation of the nonlinear polarization and the generated wave within the nonlinear crystal medium. Since we are interested in the signal processing functionality only, we approximate the generated waves as being directly proportional to the driving nonlinear polarization. This approach is valid for obtaining the generated signal forms in the case of short nonlinear crystals (limited interaction length) satisfying the phase matching condition. In practice, the temporal and spatial bandwidths, as well as the crystal length, will introduce filtering effects which will slightly modify the output signals. However, it can be shown that when wave mixing with spectrally decomposed waves, especially mutually inverted waves, the phase matching requirement is well satisfied and the filtering effects are negligible for the employed crystal lengths. In our experiments, we typically used 2 mm long β-barium borate (BBO) crystals. Using the simplified method for obtaining

the form of the generated waves, arrangements for synthesizing, processing, and detecting ultrafast waveforms can be explored.

Detection of Ultrafast Waveforms

Ultrafast optical waveforms are too rapid for acquisition by opto-electronic means alone, due to the latter's finite response time. An optical processor is usually required to convert a finite time window (typically in the tens to hundreds of ps range) to a stationary signal in space for detection by slower means. We mix two mutually inverted spectrally decomposed waves in the Fourier plane of a spectral processing device, and spatially Fourier transform the resultant wave to the output plane. As will be shown below, when one of the spectrally decomposed waves is generated by a transform limited short pulse, the output spatial signal carries the temporal information of the input waveform. We call this process a time-to-space converter.

Let two ultrafast waveforms, $s((t-t_0)/\tau)$ and $r(t/\tau)$, enter the spectral processing device from opposite directions (one strikes the grating at angle θ and the other at $-\theta$, see **Figure 4**). Each waveform will generate a spectrally decomposed wave in the spatial Fourier transform plane. The spectrally decomposed wave of the signal $s(t)$, as defined by eqn [9], yields the first input field:

$$U_1(x';t) \approx w\left(\frac{c(t-t_0)}{\alpha L}\right)\exp\left(-\mathrm{i}\frac{\omega_0(t-t_0)x'}{\alpha f}\right) \times \tilde{s}\left(-\frac{\omega_0 \tau x'}{\alpha f}\right)\exp(\mathrm{i}\omega_0 t) \quad [11a]$$

whereas the inverted spectrally decomposed wave for $r(t/\tau)$ is given by

$$U_2(x';t) \approx w\left(-\frac{ct}{\alpha L}\right)\exp\left(\mathrm{i}\frac{\omega_0 t x'}{\alpha f}\right)\tilde{r}\left(\frac{\omega_0 \tau x'}{\alpha f}\right)\exp(\mathrm{i}\omega_0 t) \quad [11b]$$

Without loss of generality, we set the time delay parameter in eqn [11b] to zero, such that the parameter t_0 in the spectrally decomposed wave of the signal waveform is a measure of the relative time delay of the two waveforms. With full knowledge of the two input waves, U_1 and U_2, we can express the resultant waveform of the three-wave mixing process as:

$$U_3(x';t) \propto P_{\mathrm{NL}}^{\mathrm{sum}}(x';t) = w\left(\frac{c(t-t_0)}{\alpha L}\right)w\left(-\frac{ct}{\alpha L}\right) \times \exp\left(\mathrm{i}\frac{\omega_0 t_0 x'}{\alpha f}\right)\tilde{s}\left(-\frac{\omega_0 \tau x'}{\alpha f}\right)\tilde{r}\left(\frac{\omega_0 \tau x'}{\alpha f}\right) \times \exp(\mathrm{i}2\omega_0 t) \quad [12]$$

Next we apply a SFT to propagate the wave U_3 to the output plane, yielding:

$$U_{\mathrm{out}}(x'';t) = \int U_3(x';t)\exp\left(-\mathrm{i}\frac{2\pi}{\lambda_0 f/2}x'x''\right)\mathrm{d}x' = y\left(\frac{2\alpha x''}{c}-t_0\right)w\left(\frac{c(t-t_0)}{\alpha L}\right)w\left(-\frac{ct}{\alpha L}\right) \times \exp(\mathrm{i}2\omega_0 t_0) \quad [13]$$

where $y(t) = s(t/\tau) \otimes r(-t/\tau)$, as the Fourier transform of a product is the convolution of their Fourier transforms (the $\otimes$-symbol denotes the convolution operation), and we use the spatial Fourier transform kernel at the doubled carrier frequency. The stationary spatial signal, $y(\cdot)$, is proportional to the convolution of the two input waveforms, where

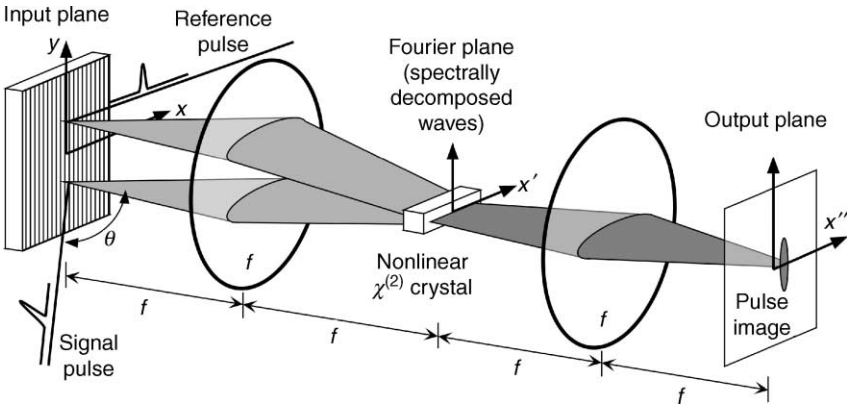

Figure 4 Arrangement for imaging ultrafast waveforms using a time-to-space conversion. The mutually inverted, spectrally decomposed waves of a signal waveform and that of a reference pulse are mixed in a nonlinear crystal placed at the Fourier plane. The generated wave is spatially Fourier transformed to the output plane, yielding a stationary image that carries the signal waveform information. © 2001 Optical Society of America.

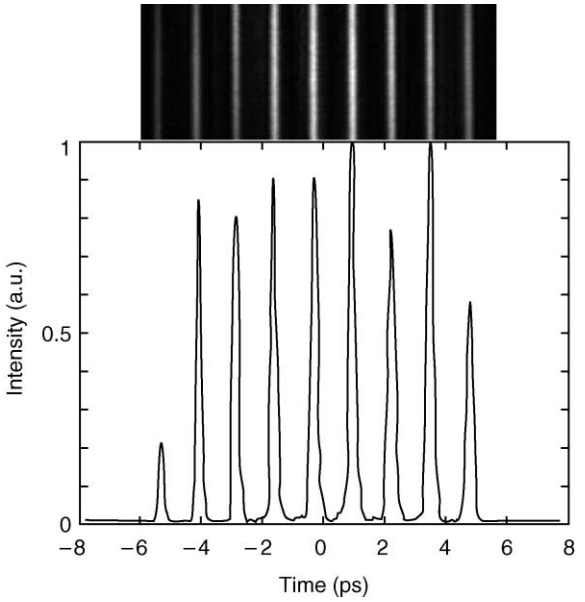

Figure 5 Output of a time-to-space converter. Top: image acquired by a CCD camera of the stationary image of a pulse sequence. Botttom: extracted time domain data from the image, showing inter-pulse time separation of 1.25 ps.

one of them is reversed in time. This mixing process was developed for time-to-space conversion by using a reference transform limited pulse for the reversed waveform. The resulting spatial image will be that of the signal waveform, albeit smoothed out due to the convolution operation with the reference pulse. The spatial signal is centered at $x'' = ct_0/2\alpha$, illustrating that the relative time delay between the two waveforms shifts the location of the output signal. The temporal characteristic is determined by the product of the time-scaled input apertures. The relative time delay, t_0, serves as an attenuation mechanism when the time windows are not perfectly aligned. When the time delay between the signal pulse and the reference pulse is too large, no output signal will emerge as the two signals do not overlap for the wave mixing process. Therefore, the time window of the spectral processing device is determined by the input aperture size, not the physical dimension of the nonlinear crystal. Consequently, we have been able to demonstrate high-resolution temporal imaging with time windows in the range of tens of picoseconds (see Figure 5). Additionally, as mentioned earlier, one of the significant advantages of this technique is the favorable phase matching condition with the spectrally decomposed wave and its inverted counterpart.

Processing of Ultrafast Waveforms

The simplest form of ultrafast waveform processing uses linear filtering, or placement of an element with transmittance characteristics that are frequency selective. However, a linear filter is a time invariant process and cannot perform more advanced processing operations of ultrafast waveforms such as interaction between ultrafast waveforms. For such processing applications, we mix three spectrally decomposed waves in the Fourier plane of a spectral processing device to generate a resultant output ultrafast waveform in real time. We illustrate advanced processing by performing a time reversal experiment using the spectral phase conjugation and spectral inversion techniques in four-wave mixing experiments.

Consider three ultrafast waveforms, $s_1(t - t_0/\tau)$, $s_2((t - t_1)/\tau)$ and $s_3(t/\tau)$, which enter a spectral processing device for generation of their respective spectrally decomposed waves. Let all three waves enter the spectral processing device from the same direction, such that the spatial dispersion is in the same direction for each signal (as defined by eqn [11a]), and generate the spectrally decomposed waves $U_1(x';t)$, $U_2(x';t)$, and $U_3(x';t)$, respectively (see Figure 6a). Since we utilize a cascaded second-order nonlinearity process, we let the first two waves interact first in a frequency-sum process, generating the intermediate field:

$$U_{\text{int}}(x';t) \propto P_{\text{NL}}^{\text{sum}}(x';t) = w\left(\frac{c(t-t_0)}{\alpha L}\right) w\left(\frac{c(t-t_1)}{\alpha L}\right) \times \exp\left(-\text{i}\frac{\omega_0(2t-t_0-t_1)x'}{\alpha f}\right) \tilde{s}_1\left(-\frac{\omega_0 \tau x'}{\alpha f}\right) \times \tilde{s}_2\left(-\frac{\omega_0 \tau x'}{\alpha f}\right) \exp(\text{i}2\omega_0 t) \quad [14]$$

It should be noted that upon a more rigorous analysis of the generated frequency-sum wave, phase matching is not well met across the temporal bandwidth of the waveform, as is the case when wave mixing mutually inverted spectrally decomposed waves. This will introduce time domain spectra filtering effects, but for simplicity these effects are ignored below. The generated frequency-sum wave interacts with the third input wave in a frequency-difference process, giving rise to the fourth wave:

$$U_4(x';t) \propto P_{\text{NL}}^{\text{diff}}(x';t) = w\left(\frac{c(t-t_0)}{\alpha L}\right) w\left(\frac{c(t-t_1)}{\alpha L}\right) \times w\left(\frac{ct}{\alpha L}\right) \exp\left(-\text{i}\frac{\omega_0(t-t_0-t_1)x'}{\alpha f}\right) \times \tilde{s}_1\left(-\frac{\omega_0 \tau x'}{\alpha f}\right) \tilde{s}_2\left(-\frac{\omega_0 \tau x'}{\alpha f}\right) \tilde{s}_3^*\left(-\frac{\omega_0 \tau x'}{\alpha f}\right) \exp(\text{i}\omega_0 t) \quad [15]$$

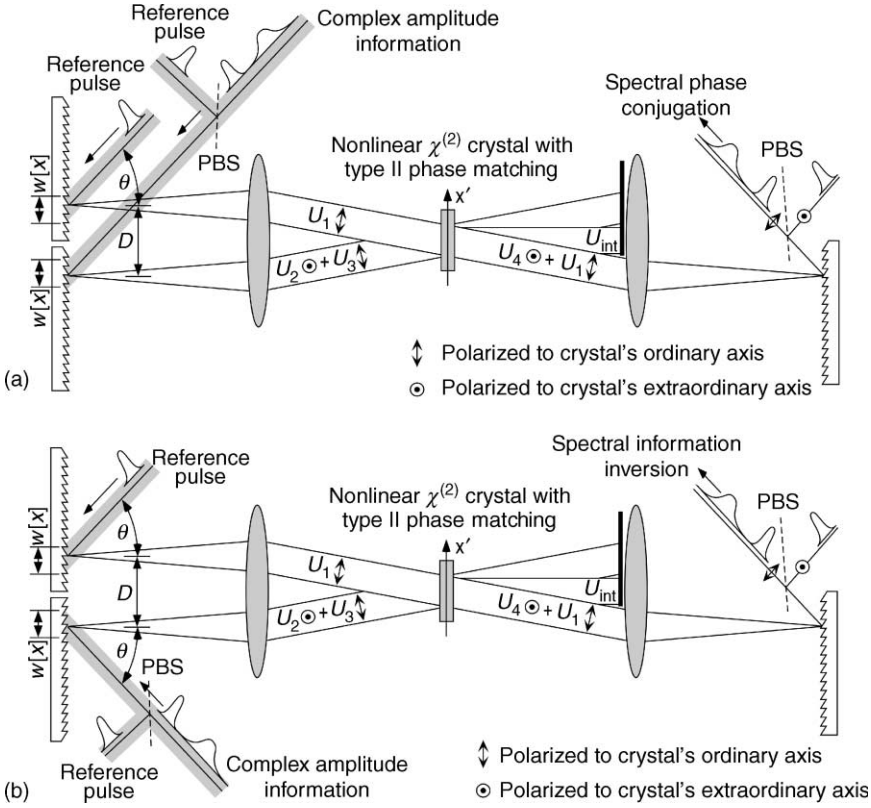

Figure 6 Arrangements of processing ultrafast waveforms within a spectral processing device. (a) Three input waveforms are introduced from the same direction, and their spectrally decomposed waves interact via four-wave mixing. (b) The three input waveforms are introduced from opposite directions, giving rise to mutually inverted spectrally decomposed waves. These two arrangements can perform time reversal, the first by spectral phase conjugation and the second by spectral information inversion. © 2001 IEEE.

where we assume that the window function $w(\cdot)$ is real. Next we apply a SFT to propagate the wave U_4 to the output plane, yielding:

$$\begin{aligned} U_{\text{out}}(x'';t) &= \int U_4(x';t)\exp\left(-\mathrm{i}\frac{2\pi}{\lambda_0 f}x'x''\right)\mathrm{d}x' \\ &= y\left(\frac{\alpha x''}{c}+t-t_0-t_1\right)w\left(\frac{c(t-t_0)}{\alpha L}\right) \\ &\quad\times w\left(\frac{c(t-t_1)}{\alpha L}\right)w\left(\frac{ct}{\alpha L}\right)\exp(\mathrm{i}\omega_0 t_0) \end{aligned} \quad [16]$$

where $y(t)=s_1(t/\tau)\otimes s_2(t/\tau)\otimes s_3^*(-t/\tau)$. The new ultrafast waveform $y(\cdot)$ scans along the output plane at a velocity of $-c/\alpha$ in the x-direction (compare to the input signals scanning in the opposite direction along the input plane, eqn [6]). By placing another diffraction grating at this plane, the new ultrafast waveform can be recomposed and made to propagate once more in free space. The waveform information consists of a convolution between the first and second signals, followed by a convolution with the third signal, which is both conjugated and reversed. If we set the first and second signals to be transform limited pulses, then the resultant waveform will carry the reversed and conjugated information of the third signal. Such capability can be very important for dispersion compensation in optical fiber communication links.

Let us now consider an alternate arrangement, where the second and third input signals are introduced to the spectral processing device from the opposite direction, and consequently have reversed spatial dispersion direction (see **Figure 6b**). Therefore, the first signal will generate a spectral decomposed wave $U_1(x';t)$, as defined by eqn [11a], whereas the second and third signals will give rise to the spectrally decomposed waves $U_2(x';t)$ and $U_3(x';t)$, with inverted spectra relative to that of U_1, as defined by eqn [11b]. The interaction of the first two waves gives rise to:

$$\begin{aligned} U_{\text{int}}(x';t) &\propto P_{\text{NL}}^{\text{sum}}(x';t) = w\left(\frac{c(t-t_0)}{\alpha L}\right) \\ &\quad\times w\left(-\frac{c(t-t_1)}{\alpha L}\right)\exp\left(\mathrm{i}\frac{\omega_0(t_0+t_1)x'}{\alpha f}\right) \\ &\quad\times \tilde{s}_1\left(-\frac{\omega_0\tau x'}{\alpha f}\right)\tilde{s}_2\left(\frac{\omega_0\tau x'}{\alpha f}\right)\exp(\mathrm{i}2\omega_0 t) \end{aligned} \quad [17]$$

which is identical to the wave mixing process of the time-to-space converter (see eqn [12]). However, in this case, we follow the first wave mixing process by a frequency-difference process, generating:

$$U_4(x';t) \propto P_{\mathrm{NL}}^{\mathrm{diff}}(x';t) = w\left(\frac{c(t-t_0)}{\alpha L}\right) w\left(-\frac{c(t-t_1)}{\alpha L}\right) \times w\left(-\frac{ct}{\alpha L}\right) \exp\left(-\mathrm{i}\frac{\omega_0(t-t_0-t_1)x'}{\alpha f}\right) \tilde{s}_1\left(-\frac{\omega_0 \tau x'}{\alpha f}\right) \times \tilde{s}_2\left(\frac{\omega_0 \tau x'}{\alpha f}\right) \tilde{s}_3^*\left(\frac{\omega_0 \tau x'}{\alpha f}\right) \exp(\mathrm{i}\omega_0 t) \quad [18]$$

Next we apply a SFT to propagate the wave U_4 to the output plane, yielding the output waveform:

$$U_{\mathrm{out}}(x'';t) = \int U_4(x';t) \exp\left(-\mathrm{i}\frac{2\pi}{\lambda_0 f} x' x''\right) \mathrm{d}x' = y\left(\frac{\alpha x''}{c} + t - t_0 - t_1\right) w\left(\frac{c(t-t_0)}{\alpha L}\right) \times w\left(-\frac{c(t-t_1)}{\alpha L}\right) w\left(-\frac{ct}{\alpha L}\right) \exp(\mathrm{i}\omega_0 t_0) \quad [19]$$

where $y(t) = s_1(t/\tau) \otimes s_2(-t/\tau) \otimes s_3^*(t/\tau)$. As before, the new ultrafast waveform $y(\cdot)$ scans along the output plane at a velocity of $-c/\alpha$ in the x-direction, and will propagate in free-space upon another grating diffraction. This time, however, the waveform information consists of a convolution between the first signal and a time-reversed second signal, followed by a convolution with the conjugated third signal. If we set the first and second signals to be transform limited pulses, then the resultant waveform will carry the conjugated information of the third signal. If we set the first and third signals to be transform limited pulses, then the resultant waveform will carry the reversed information of the second signal.

We have experimentally demonstrated the two time-reversal techniques: the first technique whereby the resultant signal is both reversed and conjugated is labeled 'spectral phase conjugation', as the signal's spectrum is conjugated by the frequency difference process, and the second technique, where the signal is purely reversed in time, is named 'spectral information inversion', as the spectrum is flipped about the carrier frequency (see Figure 7). By proper selection of the input waveforms, one can also obtain higher-level operations and functionality such as convolutions and correlations among the different signals. All these operations are time-variant, and cannot be performed by passive filtering alone.

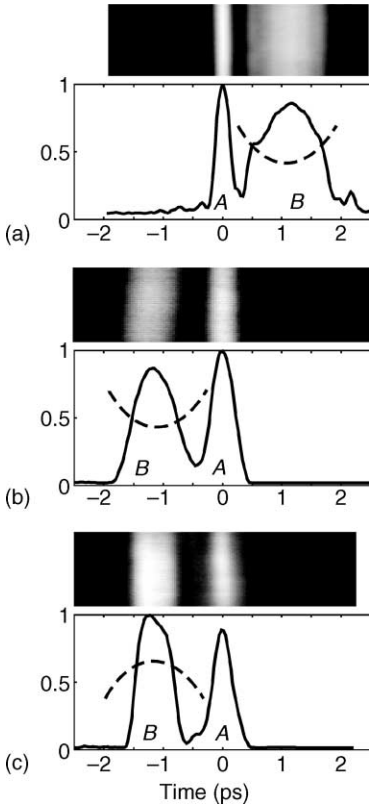

Figure 7 Time reversal experimental results. (a) Input pulse pair consisting of a transform limited pulse followed by a chirped pulse. (b) Time reversal by spectral information inversion technique. Chirped pulse leads transform limited pulse and maintains the sign of the chirp. (c) Time reversal by spectral phase conjugation technique. Chirped pulse leads transform limited pulse and flips the sign of the chirp. Synthesis of Ultrafast Waveforms

Shaping of ultrafast waveforms is usually performed by filtering an input transform limited pulse by a fixed filter. Adaptive filtering can be performed by various means incorporating opto-electronic modulators such as liquid-crystal-based or acousto-optic-based spatial light moduloators, however the response time required for changing the waveform is typically limited to the ms and μs regime, respectively. For ultrafast reconfigurability, we utilize our spectral processing device and wave mixing, to achieve pulse shaping controlled by light, or a second optical signal.

Let the three input signals entering the spectral processing device be an ultrashort waveform, $s(t/\tau)$, and two additional spatial domain signals; one carrying spatial information $m(x/\chi)$, where χ is a scaling factor, and the second a point source (see Figure 8). Both spatial domain signals are illuminated

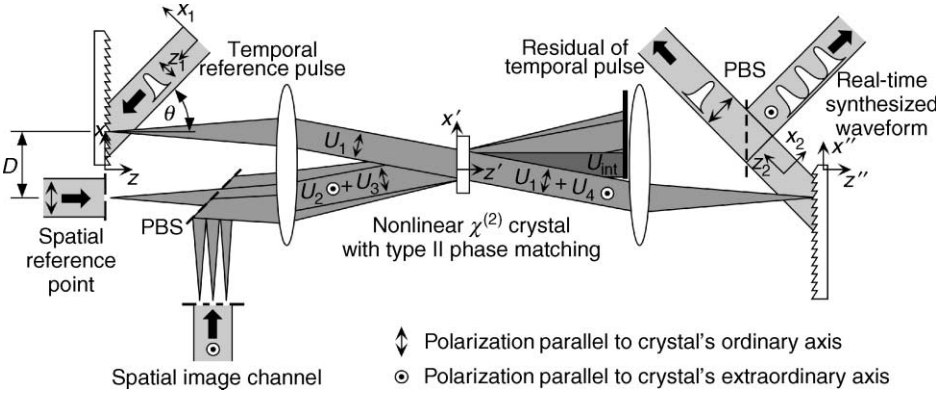

Figure 8 Arrangement for ultrafast waveform synthesis by wave mixing temporal and spatial information channels. Three input channels consist of a temporal channel, a spatial channel carrying information, and a second spatial channel consisting of a point source. The information from the spatial channel is transferred to the temporal channel via the wave mixing process. © 2001 IEEE.

by a monochromatic light source at frequency ω_0. The input ultrashort waveform gives rise to a spectrally decomposed wave $U_1(x';t)$, as described by eqn [11a]. The spatial information channel is SFT by a lens, generating the wave:

$$U_2(x';t) \propto \tilde{m}\left(\frac{\omega_0 \chi x'}{2\pi c f}\right) \exp(i\omega_0 t) \qquad [20]$$

The signal from the point source (or $\delta(x)$) gives rise to a wave $U_3(x';t)$ with no spatial information (plane wave). As before, we utilize cascaded second-order nonlinearities for the wave mixing process. The interaction of the first two waves gives rise to the intermediate frequency-sum wave:

$$U_{\text{int}}(x';t) \propto P_{\text{NL}}^{\text{sum}}(x';t) = w\left(\frac{ct}{\alpha L}\right)\tilde{s}\left(-\frac{\omega_0 \tau x'}{\alpha f}\right)\tilde{m}\left(\frac{\omega_0 \chi x'}{cf}\right)\exp(i2\omega_0 t) \qquad [21]$$

The frequency-difference process with an informationless waveform serves to reduce the carrier frequency of resultant waveform back to ω_0. The down-converted wave U_4 is SFT to the output plane, yielding:

$$U_{\text{out}}(x'';t) = y\left(\frac{\alpha x''}{c} + t\right)w\left(\frac{ct}{\alpha L}\right)\exp(i\omega_0 t_0) \qquad [22]$$

where $y(t) = s(t/\tau) \otimes m(-ct/\alpha\chi)$. As in the processing of ultrafast waveforms section above, the new ultrafast waveform $y(\cdot)$ scans along the output plane at a velocity of $-c/\alpha$ in the x-direction. The synthesized ultrafast waveform can propagate in freespace after an additional grating diffraction. The waveform information, in this case, consists of a convolution between the input temporal signal and a time-scaled and reversed version of the spatial information channel. Since the input temporal channel is typically a transform limited pulse, the output waveform carries the spatial information image, mapped to the time domain. In analogy to the imaging of ultrafast waveforms section, we call this technique space-to-time conversion. We have generated experimentally numerous waveforms that are controlled by a space domain image, or mask (flat-top waveforms, Figure 9, and pulse sequences of Figure 5 were generated by a cylindrical lens array in the spatial information channel).

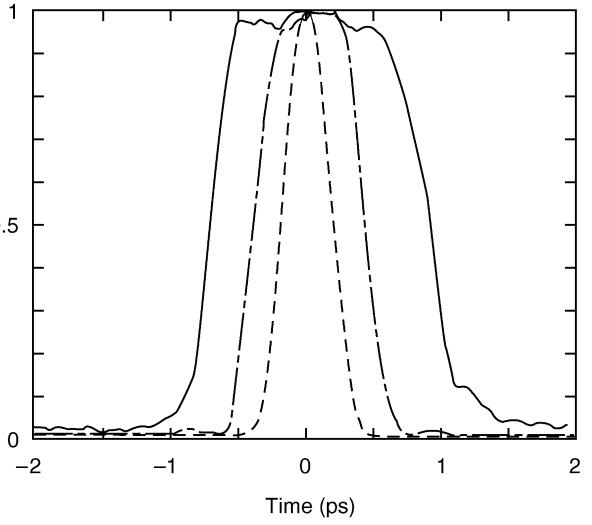

Figure 9 Synthesized flat-top waveforms via space-to-time conversion utilizing a variable slit in the spatial information channel. Increasing the width of the slit results in broader square-shaped pulses in real-time. Solid line: 2 ps pulse, dot-dash line: ~1 ps pulse, dashed line: ~300 fs pulse.

Conclusions

To properly utilize ultrafast waveforms in scientific and advanced technology applications requires instantaneous techniques from generation to processing and imaging of the waveforms. We have studied the nonlinear wave-mixing approach within a spectral processing device, and demonstrated the ability to perform all of these tasks. The wave mixing was performed in a second-order nonlinear crystal, using three-wave mixing for detection and four-wave mixing for synthesis and processing of ultrafast waveforms. The three-wave mixing process results in a second-harmonic output image, suitable for acquisition by silicon-based CCD imagers. The four-wave mixing processes result in an output waveform of an identical carrier frequency, as typically required in processing and synthesis applications. The high nonlinear coefficient of $\chi^{(2)}$ crystals enabled us to demonstrate these techniques with ultrashort pulse energies ranging from nJ to mJ levels. Further advantages afforded by the techniques are expanded time windows and favorable phase matching.

This review of the instantaneous optical signal processing capabilities with optical nonlinearities and interaction with ultrafast waveforms introduced and demonstrated the basic signal processing capabilities to manipulate optical signals in amplitude and phase. The same techniques can be used and expanded upon to achieve different signal processing abilities, which are beyond the scope of this article.

EARLY HISTORY OF QUANTUM ELECTRONICS

C H Townes, University of California, Berkeley, CA, USA

© 2005, C H Townes. Published by Elsevier Ltd. All rights reserved.

All the ideas essential to making a laser were known before 1930, but there was no operating laser before 1960. So why didn't the laser come sooner? There are several reasons. One important impediment to the laser invention was that a combination of ideas from quantum mechanics and from electrical engineering was needed, and these two fields were not well mixed in the early days. Another is that, while some physicists recognized that amplification could occur if there was a population inversion of states, they did not consider the coherence of such amplifications and did not recognize its importance or usefulness. It was just something that in principle could happen, but was not very interesting. What was required was a combination of physics and electrical engineering thinking and recognition of the coherence of such amplification. In addition the importance of such a development had to be visualized and recognized in a way that it led to very devoted work towards its achievement.

It is striking that lasers grew out of the study of microwave spectra of molecules, for which engineering and quantum mechanics were both important and which helped orient thinking in the appropriate direction. That this origin was not accidental is convincingly demonstrated by the fact that three independent ideas for amplification by stimulated emission were generated about 1950. They were from Joe Weber, at the University of Maryland, from Nikolai Basov and Alexander Prokhovov at the Soviet Academy, and myself at Columbia University. Weber primarily wanted to point out the possibility, but didn't try to do it. In addition, his numbers were a bit off and no practical system was suggested. Basov and Prokhovov actually worked towards microwave amplification using a beam of molecules, as did I.

That stimulated amplification was recognized early, but not thought through, is illustrated by the fact that Prof. Richard Tolman, a theoretical physicist, wrote a discussion in 1924 of the net absorption of light by molecules, pointing out in particular that induced emission counteracted absorption and noting that if there were more molecules in the upper than in the lower state there could be 'negative absorption'. But, he wrote, 'This would usually be very small'. The Russian physicist Vitaly Ginsburg wrote me, after the maser and laser had appeared, that his professor, S.M. Levi, had been well aware of such effects back in the 1930s and had told him 'create an overpopulation at higher atomic levels and you will obtain an amplifier; the whole trouble is that it is difficult to create a substantial overpopulation of levels'.

The German physicist F.G. Houtermans said to me that in 1932, when told by a colleague of an unusual light intensity in a gaseous discharge, he had thought it might be a 'photon avalanche', i.e. multiplication of photons by stimulated emission.

Another Russian physicist, V.A. Fabricant, wrote a thesis in 1939 in which he discussed absorption and emission of light radiation in a gas and looked for 'negative absorption', or amplification. He did not discuss coherence or a resonant cavity, and was not able to achieve any amplification so his work was quickly forgotten. None of these early mentions of stimulated emission proposed how to actually get amplification, that it would be useful, nor clearly noted its coherence. Tolman did, however, write in 1927 that, 'We should expect radiation induced by an external field to be coherent with the radiation associated with that field'. I know of no proposal to actually make use of such amplification, until those made by microwave spectroscopists in the early 1950s.

Another clear indicator that even in the 1950s physicists and engineers did not think amplification by stimulated emission was particularly interesting nor useful is that during the $2\frac{1}{2}$ years when Jim Gordon, Herb Zeiger, and I were working on trying to obtain microwave amplification (the maser), a large number of scientists visited my laboratory, saw what we were doing, but no one bothered to also try to obtain such amplification. After the maser worked, it hit the newspapers and then very quickly became a popular and intense field of interest for a number of physicists.

My own drive to produce oscillators by stimulated emission came from my strong interest in obtaining sources of waves shorter than the few millimeters wavelength which could be produced by electronic devices, in order to extend the high resolution study of molecular spectra to wavelengths shorter than microwaves, down into the far infrared. My students and I worked on several possible schemes for producing waves shorter than those produced by klystrons or magnetrons – frequency multiplication by nonlinearities, electronic beams passing over surfaces of solid materials with resonances, and anything else I could think of. None worked very well.

In early 1950, I was asked by the Office of Naval Research to form and chair a committee which would examine possible research towards obtaining wavelengths down to one millimeter and shorter. I chose outstanding scientists and engineers in a variety of fields which might touch on this problem. We met together, and visited many pertinent laboratories and individuals interested in such research. Nothing very promising seemed to turn up. But we wanted, of course, to at least provide a report summarizing the situation as we saw it. Our last meeting was April 26, 1951, in Washington, D.C. Worrying over our lack of success, I woke up early before the meeting. Breakfast was not ready, so I walked over to nearby Franklin Park, sat on a bench in front of beautiful blooming azaleas, and puzzled over why neither I nor the Committee had found any promising solutions.

I went over all the ideas I had had previously. Molecules, of course, can produce high frequencies. But I had previously concluded, I thought wisely and rigorously, that one could not obtain intense radiation from them because radiation intensity was a function of temperature, and the temperature could not be very high without destroying the molecules. Suddenly I realized that they did not need to have a temperature in the usual sense – they need not be in temperature equilibrium. There could be more molecules in an upper than a lower excitation state, which could in principle produce indefinitely intense radiation. I pulled a piece of paper out of my pocket and wrote down the equations and numbers for such a case, using a molecule beam sent into a resonant cavity and ammonia molecules with which I was very familiar. My equations said one could get enough excited molecules, low enough loss in a resonant cavity, and it would work! Why hadn't I thought of it before?!

Back at Columbia, where I worked, and about 4 months later, the graduate student Jim Gordon agreed to work on trying to obtain such an oscillator using a beam of ammonia. I assured him that if it didn't work he could modify the experiment to do interesting spectroscopy and thus complete a thesis. But we both thought he had a good chance of making it work. And a young post doc working with me, Herb Zeiger, joined the effort.

Actually, I had first thought of obtaining stimulated emission from a molecular beam back in 1948, but simply as a demonstration of physical principles rather than as a useful amplification. Also, about a year later a young post doc, J.W. Trischka, working on molecular beams with Professors Rabi and Kusch, had also thought of demonstrating stimulated emission. We talked about it together, and he decided it wasn't worthwhile just demonstrating the effect because it wouldn't really prove any new physics. Neither of us at that time had recognized the real point and the possibility of useful amplification, which is one of the reasons mentioned above that the idea was delayed as long as it was.

It is perhaps important to emphasize again and to illustrate how out-of-the-way the use of stimulated emission was at that time for physicists, and how distant stimulated emission was from engineers. While we were working on the ammonia beam maser, Prof. L.H. Thomas, an outstanding physicist known for the 'Thomas Effect', frequently would run into me in the hallway at Columbia University and say that I didn't understand, and that my proposed ammonia oscillator could not work. However, I never got a clear explanation from him of what it was I didn't understand. And after we had been working on the ammonia maser system for about 2 years (a more-or-less normal time for a student thesis project), the Physics Department Chairman, Prof. Polycarp Kusch, and the previous chairman, Prof. I.I. Rabi, came into my office to object. They were excellent physicists, both received Nobel Prizes, and both were experts on molecular beams. They sat down in my office and said 'Look, Charlie, that is not going to work. We know it won't work and you know it won't work. You are wasting departmental money, and must stop!' Other people had also questioned what I was doing, frequently in particular whether the stimulated radiation would be coherent. So I had already thought over the situation many times. I had full notes from the quantum mechanics course I took as a student back in 1938, and could derive from them a proof of coherence. I felt also that I knew the quantitative numbers, such as the molecular beam intensity and the possible 'Q', or loss, in the cavity resonator, very well. I was also by then an Associate Professor, and the department chairman could not fire me simply because of stupidity. I replied to Rabi and Kusch 'No, I believe it has a reasonable chance of working and I'm going to continue!' Annoyed, they stomped out of the room.

About 2 months after the Rabi/Kusch incident, Jim Gordon dashed into the classroom where I was lecturing and said loudly 'It's working!' Most of the class then went up to the lab to see the new device. Rabi and Kusch were not against me; even though they were outstanding physicists, they probably just didn't quite comprehend the device. A couple of months after its successful operation, Kusch more or less apologized by saying 'Well, I should have realized that you probably know more about what you are doing than I do.'

After the maser successfully operated, there were other incidences showing the lack of appropriate

focus of physicists on stimulated emission. I was a friend of Aage Bohr, the son of Niels Bohr, and in that connection was visiting him in Denmark. Niels Bohr asked me what research I was presently doing, so I told him about our new oscillator, the maser, and its remarkably pure frequency. He looked at me and said 'Oh no, that's not possible. You must be misunderstanding something.' I emphasized again what it was really doing, but he still seemed not to believe it could function that way. I presumed he was thinking in terms of the uncertainty principle and the finite time of passage of a molecule through the cavity, though I never was quite sure just why he felt it impossible. A similar thing happened shortly after that at a cocktail party in Princeton, where John Von Neumann asked the same question – what was my research at the moment? After telling him about the maser oscillator and the purity of frequency he reacted very similarly 'Oh no,' he said, 'That can't be right. You must be misunderstanding something.' After arguing a little more, he left to get another drink. Fifteen minutes later he came back, saying 'Hey, you are right!' He had understood, and wanted to talk much more about the maser and of possibly using excited semiconductors. Only after his death did I learn from his notebooks that he had considered exciting electrons in semiconductors with neutrons from a reactor, and had written Edward Teller about whether some experiments might be done with this to obtain intense light. However, he had not considered coherence, and Teller was apparently not interested enough to respond, so the matter was dropped.

The above account reminds me a bit of the amusing comments of Arthur Clark on 'Change'. He writes:

'People go through four states before any revolutionary development:

1. It's nonsense, don't waste my time
2. It's interesting, but not important
3. I always said it was a good idea
4. I thought of it first'.

It's clear that the world of physics was thinking very little in the direction of masers or lasers, and that many preconceptions as well as lack of interest stood in the way. My own experience with engineering at Bell Telephone Labs during World War II, in designing radar and electronic systems, plus my intense interest in obtaining short-wave oscillators, were clearly important in bringing me to the right ideas.

As masers became very interesting to the physics community and the field grew rapidly, my engineering experiences continued to be of help. I was well acquainted with the theoretical examination of noise in vacuum tube amplifiers by various individuals at Bell Labs, and recognized that the maser could provide much more sensitive amplification than could common electronic amplifiers, where discrete electronic charges produce the basic noise. On sabbatical in France, I worked on electron spin masers with Jean Combrisson and Arnold Honig who had the appropriate equipment. And then in Japan, Koichi Shimoda, Hidetoshi Takahashi, and I wrote a theoretical paper on the basic quantum noise of maser (or laser) amplification. The theory showed that maser amplifiers of microwaves should be about 100 times more sensitive than the existing electronic ones.

After 2–3 years of maser experiments and development I felt I wanted to move on to the shorter wavelengths for which I had generated the maser idea. Although I had first tried the idea at microwave frequencies because that seemed the easiest way to test out the general idea and the result had been exciting, I still wanted those shorter wavelengths. I had not come up with any great ideas of just how to get to much shorter wavelengths, which is why I waited several years after the maser worked before moving on. However, in 1957, 3 years after the first successful operation of the maser, I decided it was high time to simply figure out what was the best way I could imagine to move on into the infrared region and do it. A number of physicists had concluded that of course one couldn't make masers work at much shorter wavelengths, certainly not in the visible region, because spontaneous emission becomes so much faster as the wavelength is shortened and adequate inversion of population was not practical. But that was intuition, not quantitative science. As I wrote down equations for what might be done to move towards shorter wavelengths using a model of atomic or molecular excitation by radiation and a reasonably high Q resonator, it became clear that it was quite practical to move on even into the visible region. That was exciting! Why hadn't I, or someone else, looked at it carefully and quantitatively before that time?

I was at the time consulting at Bell Labs, with the assignment to spend a day there every 2 weeks and just talk with the Lab's scientific personnel. Since my former post doc and now brother-in-law Arthur Schawlow was then at Bell Labs, I of course talked with him. On telling him of my ideas for an 'optical maser', using a resonant cavity and excitation of atoms with optical radiation, he said he too was interested in that, and we decided to work together to optimize a system. It was Art who then suggested use of a Fabry–Perot resonator rather than the cavity with large holes I had used for a model, and that was

an excellent addition. Why I did not think of that is a mystery, but Art had done his thesis at the University of Toronto in Fabry–Perot spectroscopy, and that might have been why the thought came to him.

Since Art Schawlow was participating, I decided the patent for the new 'optical maser' should belong to the Bell Labs (I already claimed ownership of the basic maser patent, which covered all wavelengths). Hence we recognized that the new idea must be kept confidential until Bell Labs lawyers had worked out and applied for an appropriate patent. This delay in public information sheds some additional light on how the scientific and technical world was thinking at the time. I had written down my original ideas for an 'optical maser' in my notebook and had it witnessed by my student Joe Giordmaine at Columbia University. I had also talked with a Columbia student Gordon Gould because he had been doing research with an intense light source and I wanted to know how much intensity he had in order to be sure I could get enough excited atoms and provide an oscillator at these short wavelengths. Except for these two persons, neither Art Schawlow nor I told anyone outside of Bell Labs about the 'optical maser', or laser idea until after Bell Labs had properly prepared its patent, which was about 11 months after my first notebook entry. For that entire time, no one has produced a record of any thoughts about extending the maser to optical wavelengths except Gordon Gould, who entered some ideas in his notebook about 1 month after I talked with him about the possibility of an optical maser, and 2 months after my original notebook entry. His notes were later to be the source of a long patent case.

The striking observation is that no one outside of Bell Labs except Gordon Gould, to whom I had explained my ideas, seems to have written or noted down anything about extending masers to these shorter wavelengths during the 11 months from my recognition that it could well be done until after the Schawlow and Townes paper on how to do it became available. After that there was considerable excitement and a number of ideas.

It is also noteworthy that, because of low general interest and competition, I did not publish a paper on how a maser might be made, but waited for publication until we demonstrated its operation, about 3 years after the idea had arrived. But after the maser worked the field became exciting and competitive. Hence, Schawlow and I thought we surely should publish a theoretical paper establishing the idea before taking the time to make a laser work. And indeed, there was much competition to build the first laser.

I myself helped a couple of my graduate students start work on trying to build an 'optical maser' or laser. But at about that time (1958), I was urged to undertake a job in Washington as Vice President and Director of Research of the Institute for Defense Analysis, an organization put together largely by the presidents of several universities to try to help advise the government on matters of science and technology. Sputnik had gone up the year before, and everyone was worried about the position of the U.S. with respect to Communist Russia, which seemed to be ahead particularly in some areas important to defense. I decided I should try to help, and accepted a two-year appointment in Washington. I recognized that this seriously distracted my attention from developing a laser quickly, but knew there were many others working towards lasers and so such devices would certainly be developed and our doing it just at Columbia University was neither critically important nor highly probable.

The field of masers and 'optical masers' or lasers was becoming so exciting and a bit scrambled that The Office of Naval Research asked me if I would organize a meeting on the subject. I did, with the help of a committee of many distinguished people in the field or closely related science and technology. And it was in a meeting of the Committee that we christened the field with the name 'Quantum Electronics'. This first international meeting on the subject was at Shawanga Lodge in New York State in September 1959. It made an occasion for the Russians Basov and Prokhorov to visit the United States (and my lab and home), and was about 6 months before Ted Maiman made the first working laser. There were many interesting discussions of masers and their coming operation at optical wavelengths.

It is significant to note that, while the maser grew out of basic research in universities (with Russian work at the Russian Academy) and industry had little to do with early masers, all the first lasers were made in industrial laboratories. This illustrates the sociology and the strengths and weaknesses of industrial and of academic laboratories. While masers (and from them lasers) originated from research on microwave spectroscopy of molecules, industrial laboratories believed the field of microwave spectroscopy had little to offer in the way of commercial results. Because of equipment available and the interest of physicists in industry, the field was initiated and pursued immediately after World War II in commercial laboratories – by myself at Bell Labs, my friends at the RCA Labs, at Westinghouse, and at General Electric. For lack of interest in industry, such work was soon shut down,

except at Bell Labs, and it moved to universities. Bell Labs generously allowed me to continue such work, although they wanted me to do some 'more useful' engineering. Once the field had obvious commercial possibilities, commercial laboratories began to support it well and the clear importance of masers and lasers made industry very interested. Really interested industry can more easily put strong new resources and push harder on a field than can academic laboratories, where money has to be granted and professors have a variety of other assignments. The first laser was made to work, of course, by Ted Maiman at Hughes Research Laboratories. Ted had been a student of Willis Lamb at Stanford, and there worked on radio spectroscopy. The second type of laser, rather similar to Maiman's but using a different material, was made to work at the General Electric Laboratories by Peter Sorokin and Mirek Stevenson. Sorokin had been a student of Bloembergen at Harvard in microwave or radio spectroscopy and Stevenson was one of my students in microwave spectroscopy at Columbia University. The next type of laser, and one I particularly admire, was made by Ali Javan, William Bennett, and Don Herriott. Javan had been a student with me in microwave spectroscopy at Columbia University, Bill Bennett a student in the molecular beam group at Columbia working on radio spectroscopy, and Don Harriott was an optics specialist. All of these originators, with the exception of Herriott, had been working at universities in the field which originated the idea and were recently hired by industry. The next important laser, involving semiconductors, was invented by Robert Hall and collaborators at General Electric Labs. Note that every one of these early lasers was created in industry.

After the first laser was operated, my own students at Columbia quickly turned from trying to make a laser to using lasers to explore more physics, the normal university function. And I am delighted that masers and lasers have provided such excellent tools for research, as well as for commercial and medical applications.

After a few years of exploring new physics with lasers, I decided that since there were many excellent scientists doing such work, I should move into fields which it seemed to me were being relatively neglected. I moved to the University of California at Berkeley to look for molecules in interstellar space by microwave spectroscopy, and to do infrared astronomy. Very soon after initiating work at Berkeley, one of my students, Albert Cheung, not only discovered the first polyatomic molecules in space, he found powerful water masers. A while before our discovery of water and identification of its radiation as due to maser action, it had been deduced that some microwave radiation of OH must be due to maser action. And since then, many, many masers due to a wide variety of molecules have been found in astronomical sources as well as a few powerful lasers. Since deviations from thermal equilibrium are common in the very thin gases excited by powerful sources in space, we should have expected this, but didn't. And these masers in space could have been easily detected with radio technology available back in the 1930s if anyone had searched the microwave spectrum carefully.

Clearly, masers and lasers could have been discovered and used much sooner than they actually were. We simply were neither thinking nor looking in the right directions. And this raises the natural question – what important and more-or-less obvious ideas are we missing now because of our lack of imaginative exploration?

LET THERE BE COHERENT LIGHT: THE DISCOVERY OF THE LASER

T H Maiman, Vancouver, BC, Canada

© 2005, T H Maiman. Published by Elsevier Ltd. All rights reserved.

Editor's Note

The discovery of the first laser was a remarkable culmination of human creativity and ingenuity. However the achievement was finally made by one individual young scientist, Theodore Maiman, working independently of the mainstream and without the benefit of strong government or private financial support. With persuasive arguments, he convinced his management at the Hughes Research Laboratories to allow him to continue his work, albeit with limited resources. And then, working alone with his assistant he saw the light that now illuminates the world of laser science and engineering. This is the story of how thinking outside the box created a new field of science, whose developing technology has advanced the state of medicine and engineering and the quality of life in general.

Introduction

I am frequently asked how it was that I discovered the laser. Many assume that the concept evolved from some sudden, inspirational thought. It didn't happen that way.

It is dramatic and exciting to have a scientific discovery emerge from a dream or a vision that comes out of nowhere, but it seldom does. In reality, almost all scientific discoveries come from building on other, prior, scientific developments.

So it was with the laser. In 1916, Albert Einstein laid the foundation and conceived the basic underlying principles on which lasers are based. He formulated and explained the relations that govern the way that atoms and molecules absorb and emit radiation. He introduced the key concept of stimulated emission. Then, in the 1920s, physicists C.H. Füchtbauer and Rudolph Ladenburg added formulations that used the Einstein theory to go further, and tie the absorption of light in a material medium to the fundamental properties of its constituent atoms. But it was the Russian physicist A.V. Fabricant who first had the vision to propose the concept of a laser in 1940.

Unlike the Sun and other incoherent light sources, the laser produces light of one precise color. Its waves are emitted in phase with each other, and its radiation can be efficiently focused to a precise spot. In short, the laser produces coherent light, with the properties we were already used to with radio, television and microwave sources.

Fabricant specified the conditions needed for amplification of light via stimulated emission. He appreciated the concept of an inverted population and the concept of coupling such an inverted population medium to a resonant structure (resonator). He proposed using a gaseous electrical discharge to achieve laser action as one possibility. Later, he proposed the use of a helium discharge lamp to optically pump the gaseous form of cesium.

Scientists Purcell and Pound were the first to report evidence of net stimulated emission in 1951. Their observation, in the radio part of the spectrum, was a by-product of their pioneering developments in the techniques of nuclear induction, the foundation for magnetic resonance imaging.

The first achievement of a working device that utilized stimulated emission as its operating principle was a microwave oscillator/amplifier. That device used a beam of ammonia molecules as the working medium. The design details were worked out independently by groups at the Lebedev Institute in the Soviet Union and Columbia University in the USA. The device was dubbed a *maser*, which is an acronym for *microwave amplification by stimulated emission of radiation*.

In 1955, the year after I was awarded my Ph.D., I joined the Hughes Research Laboratory in Culver City, California. One of my major assignments was to head a project developing a miniature, liquid-nitrogen ruby maser for the US Army Signal Corps.

Race to the Light

Before starting work on the maser I had begun to germinate some ideas about the possibility of a laser. My concept so far was to try to use a solid material for the lasing medium, and to fabricate the potential laser material into a rod shape. In microwave thinking this configuration would be called a *dielectric wave-guide*. In optics it is known as a *light pipe*.

Abridged from "The Laser Odyssey" by Theodore H. Maiman. Copyright © 2000 Theodore H. Maiman. Reproduced with the permission of the author and Laser Press, Blaine, WA, USA.

I planned to put mirrors on each end of the rod to form a resonator.

Despite the advances in physics it represents, the maser does not in any way extend the coherent electromagnetic spectrum. Furthermore, its use as an amplifier turned out to be impractical because cryogenic temperatures were required for proper operation. There was strong motivation to push the frontiers of coherent electromagnetic radiation to higher frequencies, principally the promise of higher energies and greater concentrations. The reduction in wavelength from microwave to visible is a factor of about 10^4. This would lead to a consequent 10^4-fold reduction in the minimum achievable focal size, and a 10^8-fold increase in energy concentration delivered by the laser.

Work on the maser project therefore proved something of a distraction, and it was not until August 1959 that I was able to devote full effort to the consideration and analysis of my concepts for a laser.

Why would I be willing to enter such a race? There was rather formidable global competition already in play, well-funded and very competently manned. The answer lies in my knowledge of the proposals that had been floated about. Generally, the scientists who pursued these notions were not particularly secretive about what they were working on. They published and gave talks at conferences. On the whole, however, I found that the authors and conference presenters were only offering vague proposals. To be sure, this served as an exchange of information and stimulated ideas. But it didn't appear to me that anyone was close to the answer. In short, no viable laser concept was yet in existence.

As I look back, I was a little brash. I would be thrusting myself, in a sense, into a technological Olympics. The competition was of the best quality and of international scope. But my competitive spirit won out. The challenge of working in the top league of such an exciting project, that had so many questions and problems to resolve, was very compelling to me.

We know *now* that many kinds of lasers can be made. But back then, in 1959, we didn't know. We didn't even know with any confidence if it was really possible to make a laser at all. My strategy was to limit myself to potential solutions to the making of a laser that did not have appreciable distractions in the design. That way I could focus strictly on just the laser problem itself.

For various reasons I was reluctant to work on alkali-vapor or gas discharge systems. I chose to work with solid-state crystals. The main appeal that solids held for me was simplicity. By that, I mean simple in analysis and understanding, and simple in device conception.

In contrast to a gas discharge, the energy level diagram in an appropriate crystal is very limited. There are relatively few possibilities for the energy states, and by and large, the pertinent parameters for a potential laser candidate are amenable to a combination of calculations and relatively straightforward direct measurements.

Another advantage, in principle, to a solid crystal is its relatively high gain coefficient. By that, I mean the amplification in a given length of material is of reasonable proportions. This meant that the laser medium could be relatively small in size and short in extent, and I would not have the problem of developing or depending on the use of special mirrors. Indeed, my first laser used a crystal that was only 2 cm long.

I was also intrigued with the concept of a solid medium since I would not have to deal with vacuum pumps, impurity problems and gas handling apparatus, or complex mirror mechanisms. I could put simple silver mirror coatings directly on the crystal as I had done with my small ruby maser. In principle, a solid crystal laser could be designed to be very simple, compact and rugged.

My first choice to study and contemplate was that of a ruby crystal. Ruby is the result when a water-clear cast of aluminum oxide is doped with a small amount of chromium oxide impurity. It is the chromium that is responsible for the red color. The rubies used for devices are usually not natural gemstones, which have a chromium impurity level of about 0.5%. The chromium concentration in device rubies is around ten times less than this, and hence they display a lighter red color than gemstone ruby and are referred to as *pink ruby*.

Why choose ruby as a potential laser candidate? Most importantly, I was quite familiar with and fascinated by the interesting optical properties of the crystal. Ruby is a fluorescent mineral; if ultraviolet light is shone on a ruby, it will glow with deep red fluorescence. Furthermore, ruby also gives off a red glow when either blue or green light is shone upon it. It is these blue and green absorption bands that give ruby its red color. When a green photon impinges on and is absorbed by the ruby, a chromium impurity ion is raised from its ground state into a broad, excited band. Although the chromium ion has the possibility of radiating by spontaneous emission from that excited level, another process comes into play. The competing process uses the thermal vibrations of the crystal lattice to interact with the excited ion and deposit most of the excitation energy to another slightly lower excited level of the ruby chromium

where it stays for a while. This latter process is much more probable and dominates.

The energy from this third level is radiated as spontaneous incoherent emission. This spontaneous emission is made up of red photons and is the observed fluorescence. The level where the fluorescence emanates is sometimes called a metastable level, since the chromium ions linger in that energy state for a comparatively long time before they radiate red photons.

I developed a model that could be mathematically analyzed and I set up kinetic equations to take into account the various mechanisms taking place in the fluorescent process. I also set up simple intuitive criteria for establishing the condition for laser action. This model and these equations have subsequently become a standard way for others to analyze crystal lasers.

I was able to determine which material parameters were important and relevant to a laser by getting the solution to the equations describing the model. Using known and estimated values for the pertinent parameters in ruby, I found that ruby would require a very bright pump lamp to excite the crystal sufficiently to allow laser action to take place. The brightness of a lamp is an important parameter for lasers. It is a measure not of the total power radiated by the lamp, but rather the power per unit area.

Obstacles and Solutions

Ruby has many desirable qualities. It is a very stable, very rugged crystal to work with. It has some broad pumping bands that make it helpful to get a reasonable energy transfer from an incoherent pumping lamp, and compared to some other crystals I considered (e.g., gadolinium-doped crystals), a working ruby laser would produce visible light.

However, there was some uncertainty over the crystal's measured quantum efficiency. The quantum efficiency for a fluorescent crystal is the number of fluorescent photons emitted, divided by the number of pumping photons. In the case of ruby, this is the number of red photons radiated out compared to the number of green photons absorbed. A report in November 1959 had suggested that ruby's quantum efficiency was only 1%. This would effectively mean that it would be impossible for ruby to achieve laser action. However, I was able to make my own measurements of ruby's fluorescent efficiency, and these showed that it was nearer 75%.

I now had enough information that I could proceed to work out an actual laser design. But how would I pump the ruby? What would be the ruby's shape and size?

I knew that I needed a very bright lamp. Among the brightest around was a high-pressure mercury arc lamp manufactured by General Electric. In addition to being one of the brightest available laboratory lamps, it had the advantage of radiating most of its energy in the green and blue-violet parts of the spectrum. This was a good match to what I needed for the ruby.

I drew up a paper design with the mercury arc lamp at the focus of an elliptic cylinder. A small ruby rod was to be mounted on the other focus of the elliptic cylinder. It is a property of an elliptically shaped reflector that a point of light placed at one focus of the ellipse will be imaged at the other focus. The elliptic cylinder that I had in mind would be highly polished on its inner surface to a mirror finish.

But I had a problem. My paper analysis of the design showed that although it should work, it would only do so by a slim margin. I studied the design in more detail, looking for ways to optimize and improve it, but I couldn't convince myself that it was anything but marginal.

I stewed over the problem at hand. I started to think about other ways to look at the problem. I was frustrated: I felt that, on the one hand I was very close to an answer, but on the other hand it was eluding me.

I went back to my analytical model. I pondered my options and decided to put the pumping lamp requirement for the ruby in a different form. I calculated the equivalent black-body temperature of a suitable pumping lamp. The temperature I calculated to have enough brightness capable of driving a ruby into laser action was close to 5000 K. By contrast an ordinary tungsten light bulb has a brightness temperature of about 2800 K.

Once I put the pumping requirement in terms of brightness temperature, I began to think in a different way. I remembered reading an article about photographic strobe lamps, a camera's flash mechanism. The article said that strobe lamps could reach brightness temperatures of 8000 K or more.

I now had my 'aha'!

Most scientists had been thinking in terms of a continuous laser, and that was certainly my thinking to start with. But why should I place such restrictions on myself? At this juncture I was only trying to demonstrate that coherent light could be made at all. Besides, a pulsed source is not only acceptable in many applications, it may even be preferable.

I went back to my analytical model, modified the equations to account for a pulsed light source, and then analyzed the results to guide me in the actual laser design. I had already determined that the most important parameter of the light source would be its

brightness, that is, a lamp that maximized the power per unit area into the useful pump bands of the ruby.

My calculations also instructed me that this lamp brightness requirement is largely independent of the ruby crystal dimensions and its chromium concentration over a reasonably wide range. The model assumption was that of a three-level system (appropriate to ruby) where the lower laser-energy level is the ground state.

Next, I scoured every flashlamp catalogue that I could find. I calculated the luminous intensity for promising candidates and found that the highest intensity came from three General Electric spiral-shaped flashlamps. My calculations showed that I would have an adequate margin of safety, in terms of excess brightness intensity for the laser, of some two to three times, even with the smallest lamp.

Let there be 'Coherent' Light

Based on my most current calculations and measurements, I was becoming optimistic about the possibility of creating a laser. The tension was building and I started to have dreams that I actually did it. It was a wildly exciting thought!

Still, I was worried that I might be missing something. Instead of proceeding directly to the actual design, I decided to do an experiment that would check the validity of my model.

I made up a cube of pink ruby with each dimension equal to one centimeter in length, about the size and shape of a sugar cube. The crystal axis was perpendicular to one set of faces of the cube. I then placed the cube between two parallel plates, thus forming a microwave cavity. The cavity resonance was designed to be equal to the natural ground-state splitting of the ruby. These are the ground-state sublevels used in a ruby maser.

The purpose of this arrangement and the subsequent experiment was to monitor the ground state population of the ruby. My calculations had shown that it would be possible to substantially reduce the ruby ground state ion population necessary to make a laser, but I wanted tangible evidence to confirm and justify my optimism.

I was still harassed by the thought that no one had yet ever made a laser, although by now several teams of scientists had been diligently working away for nearly two years. Was there a fundamental insurmountable problem that I had missed?

I proceeded with the experiment using the ruby cube. As described above, one set of parallel faces of the cube served as the resonant microwave cavity. I connected one of the open (second set of) faces of the cube to one end of a polished quartz rod called a light pipe. The other end of the light pipe was connected to the flashlamp. The third set of faces of the cube was used to probe with selected wavelengths of light. I used the 'loading' on the parallel-plate microwave cavity to monitor the ground state population of the ruby, making use of the microwave properties of ruby that I had learned from my work on the ruby maser.

When I flashed the lamp, the cavity loading did indeed change. It decreased because, as expected, there were fewer chromium ions in the ground state. More important, the *magnitude* of the population change, 3%, was very close to the value I had predicted from my analysis of the experimental parameters. This was an extremely gratifying result since it gave further confirmation to my model and its analysis.

Now I was getting more excited. Since I couldn't think of anything else to check, it was time to proceed with the definitive design of a laser.

The Laser Design

My first thought was to use some modification of the elliptic-cylinder configuration that I considered for the mercury arc lamp as discussed in the previous section. The problem was, I would need a straight, rod-shaped flashlamp, but the straight lamps in the catalogues that I checked didn't have high enough intensity. Therefore, I resorted to a different design and stuck with what was available – the spiral-shaped lamps. I didn't want to get sidetracked at this time into the development of a special lamp.

It dawned on me that I would not have to devise a focusing arrangement, since the brightness of the radiation that is attainable at the focus of a mirror or lens can only approach, but not exceed, the brightness of the source. So, why not just place the crystal in close proximity to the lamp? That is, why not place the crystal *inside* the lamp helix?

To help gather the light, I placed a polished aluminum cylinder around the outside of the spiral. To fit the lamp, I used a pink ruby crystal in the shape of a right circular cylinder rod, about 1×2 cm. The ends of the ruby cylinder were polished flat, parallel to each other and perpendicular to the axis of the cylinder. For mirrors, I used evaporated silver.

I chose silver for the mirrors because it has the highest reflectivity of any metal at the deep red ruby laser wavelength. However, silver tarnishes quickly, and so with time, the thin output layer will change its transmission characteristics; it is not stable. To solve this problem, I had a thick layer of silver evaporated on both ends of the crystal and I scraped a tiny hole in the coating at one end. The laser beam would emanate from that coupling hole.

The Crucial Test

As I neared completion of my laser design, Bob Hellwarth, one of my colleagues in the Atomic Physics Department, asked, 'How will you know if it's working?'

At first, I was concerned that if I were stuck with a ruby crystal that deviated too much from optical perfection, these imperfections could prevent measurable laser behavior.

To get a better understanding of the processes, I elaborated on my existing analysis to account for an imperfect crystal. I found that if I were able to drive the ruby crystal reasonably far above the point of inverted population, or laser threshold, that I would see very substantial evidence of an inverted population and impressive laser behavior even with a poor crystal.

Just exactly what would I see?

I planned to monitor the red light emitted from the ruby through the hole in the output silver coating and expected to observe three kinds of laser behavior evidence: a reduction in the decay time of the fluorescent level; the bunching of the radiation into a beam; and a significant reduction of the spectral width of the red light.

The Laser Process

Laser action can be understood by following through the operational details in the above-mentioned ruby laser design. The process starts when the ruby crystal is excited by the flashlamp and chromium ions are excited into the metastable fluorescent level. The ions lose energy by radiating randomly red photons. This is the familiar red fluorescence (spontaneous radiation).

When the excitation level is great enough, that revered 'inverted population' condition is reached. In that case, more chromium ions are in the ruby's metastable upper fluorescent level than are in the ground state. Therefore, chromium ions can radiate by *stimulated* emission as well as by the normal spontaneous emission process.

Because the metastable level now empties much faster than it normally would, the fluorescent lifetime is reduced. That decreased lifetime can be observed by monitoring the red ruby glow with a photoelectric cell connected to an oscilloscope when the ruby is flashlamp-excited.

When the ruby is in the inverted population condition, as explained previously, it becomes an amplifier. The red photons are amplified as they progress through the crystal.

An important selection process starts to take place. The red photons are initially emitted in random directions. But the fluorescent photons that happen to be radiated at large angles to the mechanical axis of the ruby cylinder are lost through the sides of the crystal. On the other hand, photons radiated along the crystal axis, or at small angles with respect to the crystal axis, are in effect, trapped. They are reflected when they strike either one of the end mirrors and move back and forth through the crystal. As these axial photons move through the ruby they are amplified and consequently generate more photons in the same direction. They quickly become the dominant stimulated radiation from the excited metastable level.

Keep in mind that photons moving through the crystal are responsible for the stimulated emission. The axial photons pick up a following and march down that crystal axis. Consequently, the photons that emerge from the coupling hole in the output silver mirror are concentrated in a direction along, or nearly along, the crystal axis.

The red ruby fluorescent (spontaneous) emission extends over a distribution of frequencies in a curve that resembles a bell shape. The fluorescent photons are most concentrated at the center of that curve. When the inverted population condition exists, the top of the curve has the highest amplification. The consequence is (as with the discussion of beam angle) that photons near the center of the distribution are favored, since it is these photons that get amplified most in the back and forth transits, through the crystal from the multiple mirror reflections. It is this last process that explains why the frequency distribution, the linewidth of a laser, is so small.

I planned to vary the excitation to the flashlamp. In doing so, as explained above, I would expect to see a reduction of the fluorescent lifetime giving evidence of stimulated emission. As I varied the ruby excitation level, the fluorescent intensity should increase proportionately, as long as I was below threshold. But, when above threshold, small increases in excitation should make much bigger changes in the output since the detector and monochromator combination are more responsive to the smaller beam and narrower linewidth.

Do it!

It was the afternoon of May 16, 1960; it was time to confirm or deny all the fears of why 'ruby can't work' or why 'lasers can't be made to work.' No more new calculations, no more diversionary experiments. This was the moment of truth!

The laser head was mounted on a workbench. The flashlamp was connected to the power supply. The trigger electrode was connected to the spark

coil (the mechanism that initiates the flash from the strobe lamp). The light output from the coupling hole in the end of the ruby was directed through the monochromator to a photomultiplier tube. The electrical signal from the photomultiplier was connected to an oscilloscope.

Irnee D'Haenens, my laboratory assistant, and I were the only ones performing and observing the experiment. We first took a test shot so that we could adjust the monitoring equipment. We turned the power supply up to about 500 volts. We fired the flashtube. Indeed, we observed a trace on the oscilloscope!

The trace was a recording of the red ruby fluorescence. The decay in the trace was about three milliseconds, the lifetime of the upper possible laser level. We made the appropriate adjustments to optimize the monitor display.

We continued. We progressively increased the supply voltage, each time monitoring and recording the light output trace. As we did so, the peak output increased proportionately to the energy input, the decay time remained the same. So far, so good.

But, when we got past 950 volts on the power supply, everything changed! The output trace started to shoot up in peak intensity and the initial decay time rapidly decreased.

Voilà. This was it! The laser was born!

The Light Fantastic

When Irnee and I observed the first laser go into action, Irnee was smiling and jumping up and down with glee. I was numb and emotionally drained from all the tension and excitement.

Imagine: in the 10 years prior to the laser, the coherent electromagnetic spectrum had been extended by perhaps a factor of five. Now, with the advent of the laser, there was a quantum jump in that spectrum of ten thousand!

The significance of my historic accomplishment didn't sink in right away. I'm not sure that it has yet.

THE HELIUM–NEON LASER

A Javan, Massachusetts Institute of Technology, Cambridge, MA, USA

The date, twelve of December nineteen sixty, and the time, 4:20 PM, are the date and the time of an event that triggered such an imortant segment of what has now evolved in modern optics. Here is how:

It had snowed heavily on that day. The laboratory at Murray Hill, New Jersey, the Bell Telephone Laboratory, BTL, had been closed at 4. What occurred was a triumph of our depth of understanding of the atomic spectra, the physics of the inter-atom collisions and electron impacts and exchange effects, the fascinating sequence of what takes place in a *gas discharge plasma* when the discharge is switched on. The triumph was also that of the art in spectroscopy, this time that of the colorful glow of a gas discharge plasma in a controlled mixture of helium and neon. Performing the spectroscopy, one could *effectively* watch and follow a set of fascinating physics effects in the discharge plasma, that would lead to an *inversion* to set-in in a specific transition between a high-lying pair of energy levels in neon, by the now well-known transition at 1.15 μm wavelength in neon. Helium atoms in a metastable state in the discharge plasma played the key role.

On that day: The laser had already been de-gassed for 5 days and nights at 600 °C under the high vacuum, to drive off the impurities prior to introducing the gas mixture in the laser-plasma quartz tubing and sealing it off. We had a way to optimize the mixture, at the exact mixture ratio for the optimum inversion and the laser gain at the 1.15 μm neon transition wavelength. The laser design had a *daring* interferometer length *one meter long*. Why *daring* at *one meter long*, I will have a chance to explain why below. The laser-mirrors at each end of the one-meter-long interferometer were situated internally in the laser, exposed to the gas mixture. Two fine micrometers at each end of the laser provided the fine control for the laser–mirror alignment control externally.

To convey the scene, we had known already, that the inversion and the laser gain at the 1.15 μm neon transition will be *higher* in the discharge '*afterglow*', the afterglow following *rapidly switching-off the discharge*. The inversion and the laser gain at the 1.15 μm wavelength, we knew, would last for as long as a millisecond in the afterglow. Certain that the inversion and the gain will be higher in the afterglow, we had set-up the electronics to switch on the discharge for about 10 milliseconds, and switching it off fast at a one microsecond switch-off time, and leaving it off for the same 10 milliseconds time interval, and repeating it at a low rep-rate, about 20 times a second on that day. Expecting that while searching for the laser signal, the laser will first break into oscillation in the afterglow where the laser-gain will be higher, knowing that pulling it into the glow afterward will be easy.

With me on that day I had two of the three good people who worked with me on the experiment. One of the two, Donald Herriott, was about to miss his car pool. He had his hand at the time on the laser–mirror tuning-alignment, the fine micrometer at one end of the laser interferometer on his side. I had my back towards the oscilloscope that would display the laser signal, aligning the detection system. My journey had begun over two years previously. I was *certain* on that day, and at that time, that possibly right then, or no later than hours later or by midnight, the moment would come for me and others that I had with me, to witness the onset of the event sought after so hard. And then … .

I had my back towards Don Herriott, urging him to stay a bit longer. I heard Don's voice, saying '*What is that*?'. I turned and looked. The laser signals in the discharge afterglow on the oscilloscope screen, synchronized to the gas discharge rep rate. I reached the laser interferometer fine-tuning micrometer on my end … a gentle tuning, in a mere few seconds time, optimized the afterglow signal, and then pulled the laser signal right into the glow. I loudly called on 'Ed' to switch on to CW. He, Edward Ballick, jumped over the equipment and the electronics on the floor in the lab, reached the switching electronics, switched it on to CW:

> The laser signal on the oscilloscope … switched to CW … a coherent light beam … CW … continuous … and at a degree of coherence … that as it proved later and I know then … to the limits that the laws of nature will permit. I looked at my watch, 4:20 PM.

The year 1960 was the beginning. Some months earlier, in the summer of that year, Theodore Maiman at Hughes Laboratories, in Malibu, CA, succeeded to operate an optically pumped laser, operating in short-duration laser pulses, the Ruby laser at 0.694 μm. That approach to the laser differed fundamentally

from the discharge plasma approach. The two were different inventions and served different purposes. One, the *optically pumped*, converts the *optical energy* in the pump, to the laser light output. The other, *electrically pumped*, converts the *electrical energy* in the *electrical current* that excites the laser plasma, to the laser light output. The rest on how things evolved is history.

The Scene Before Lasers

Before lasers, optics had long passed its peaks. The last words had been written by Born and Wolf in 1957, in an impressive volume on Physical Optics. When I went through my graduate studies at Columbia University in the early fifties, there were no graduate courses offered in optics. The subject was dealt with incidentally in courses in electricity and magnetism. Action was all on the microwaves at the time. Optical spectroscopy had reached its peaks much earlier yet, before World War II. Condon and Shortly had written the last words on Theory of Atomic Spectra in 1935, amazingly, as it seems, in *hardly a decade* after the discoveries in quantum mechanics. As events had it, optics gave way to the microwaves after the war, and optical spectroscopy to the RF and microwave spectroscopy – and all this, a result of the discoveries in Radar at the microwave frequencies in World War II.

We owed everything we knew of the atomic spectra to the *gas discharges* used as spectroscopic light sources at the time, from the high-resolution spectra of the hydrogen atoms at one end of the periodic table, to that of the trans-uranium elements on the other. We need not be reminded, everyone knows, how much we owed then and do now, to the high-resolution spectra of the hydrogen atoms, all because of the early hydrogen discharge light sources and then at the beginning, what led to the discovery of the quantum mechanics, and the wave nature of the atoms. The excitement that followed has remained unparalleled in physics since. Within hardly a decade after as a result, the cleverly designed spectroscopic gas-discharge sources, of different makes and designs, exhaustively revealed every feature predicted by the quantum mechanics in the high-resolution spectra of every element we know in nature. Gas discharge light sources set the course at the time, as did the lasers after the events in 1960.

Optics had given way to the microwaves in the fifties after the war. The physics of the gas discharges, however, continued as an active research field after the war, although of short duration. Bell Telephone Laboratory had a most distinguished research department in gas discharges in the early fifties. Towards the late fifties, as it seemed, the gas discharges as a field in research, also seemed to have been exhausted. The payoff at the time had evolved in the colorful neon light sources and fluorescence lamps, a thriving industry all over the country.

In the summer of 1958, Bell Telephone Laboratory had dissolved their research department in gas discharges. They had transferred every one of their distinguished research people to the other research areas in the laboratory. Some good people had left earlier, already.

As the fate in gas discharge physics had it, I joined the Laboratory in September 1958 – with ZERO backgrounds in gas discharge physics. I knew physics.

How Things Evolved

It has been said that when time is ripe for a new idea, if one person misses it, the next one will not. Time was ripe in the late fifties for the optically pumped idea for the laser, but far from it for the *electrically pumped*. Optical pumping was an active field in research at the time. The French had introduced the 'pompage optic', the optical pumping. With the French pompage optic, one would by optical pumping, resonantly excite an atomic species from its ground into its excited electronic state, and perform a double-resonance at an RF frequency on a fine or hyperfine structure of the excited electronic state. There were other versions of the French pompage optic. Each version used the optical pumping to induce resonantly, an atomic species into an excited electronic state.

Important, and more so, in the fifties, in the second half, the discoveries of the three-level masers at the microwave frequencies had attracted much attention. The three-level masers are the counterparts at the microwaves of our now optically pumped lasers. In three-level masers, one drives to saturation a pair of energy levels at microwave energy-spacing in a paramagnetic solid, and allows the inversion and the gain to set-in in a transition to a low-lying third energy level at the microwave frequencies. Nicholas Blumbergen at Harvard had proposed the three-level maser idea in an important publication in 1956. I had my own original three-level maser ideas, and had them published in 1957. In my work I had discovered a fascinating new effect, and for the first time, that in the transition to a third level in a three-level maser, it will be possible to drive the maser into its self-oscillation, *without* requiring the inversion. The effect had led me to the idea of the Raman masers, requiring a '*pumping*' microwave field, followed by a Raman transition across a pair of energy levels at microwave energy-spacing. In my publication of the

effect, I had also considered the pumping field at an optical frequency, instead of at the microwave.

The ideas were 'in the air' at the time, to extend the three-level maser approach into the optical frequencies. Yet, in the summer of 1958, on an occasion in June of that year, I think on the first Monday in June, *flashed* through my mind a far different approach, all because of the *helium metastables*. Ideas always come to mind in a *flash*, the rest follows.

Summer of 1958: A Bit of History

I think it was on the first Monday in June 1958. I had been on an occasion visiting the Bell Telephone Laboratory (BTL) on that day. They had approached me that I join their research staff at Bell. My work on masers – I had done as a part of my post-doctoral research position in physics at Columbia University in New York City – had in part overlapped the then ongoing work at Bell. They knew me, and I knew Bell.

At the visit meeting with Arthur Schawlow, whom I knew well, he gave me his news on that day, that he and Charles Townes, had submitted to the *Physical Review* a paper for publication proposing an optically pumped counterpart of a three-level maser at the optical frequencies – by-now, the well-known Schawlow–Townes optically pumped laser publication. Specially, I was attracted to Schawlow's idea on a two-mirror Perot–Fabry-type interferometer as a resonator at the optical frequencies for the laser. The use of it in that publication was Schawlow's idea.

My thoughts, it may seem paradoxical, right there and then moved far away from an optically pumped laser as a possibility. The helium atoms in a *metastable state* flashed through my mind. I will avoid explaining why or how, other than, of a three-level atom, two of the levels were now to belong to a *different* atomic species, the helium atom, and that there will be no optical pumping … and so much '*electrical energy*' could be converted to and stored in the energetic metastable helium. A new possibility presented itself, with no resemblance to the optical pumping – an energy-exchange effect taking place resonantly, between the highly energetic helium metastables, and – as it evolved – another inert gas, the neon atoms in a helium–neon gas mixture. The resonant nature of the effect embodied everything we know of the wave nature of the atoms. I will have a chance to explain the effect shortly below.

Driving home at the end of the day on that day, a two hour drive from Murray Hill, New Jersey to uptown New York City, the thought of the metastable helium had crystallized before me the task to examine the effect in a helium-plasma in a gas discharge, in a gas mixture with the other *four* well-behaved *inert gases*, from neon through xenon. There are four.

Within weeks in June, searching through the literature I learned, that over the years, and mostly in the early fifties, the helium plasmas in a gas discharge in mixtures with *every other* inert gases had been the subject of most extensive research, *except in a mixture with neon*. The mixture with neon, for the reason that the reader will find below, had been thought of as *uninteresting*. The matter was left for me.

I had accepted in June already, to join the Bell research staff at Murray-Hill, and I did on September. From my work that entire summer, unfolded the entire theory for the helium–neon gas laser. There was also another far-reaching offshoot.

The Physics Effect

Next to the hydrogen atom, the helium is the most fundamental of all atoms in physics. Hydrogen has one electron. Its spectrum, detached from the complexities of the multi-electron atoms, carries the entire signature of the wave nature of the atom, in ways that are subject to accurate predictions and the measurements. The helium atom has two electrons. Its spectrum carries the entire signature of the physics effect of the entire multi-electron atoms, also in ways that are subject to accurate predictions and the measurements. In its metastable states, it carries special *dynamic features*, deeply fundamental, and special *only* to the helium metastables.

In a gas discharge in pure helium at a moderate gas pressure, the discharge color takes on a grayish-white with a tint of blue. Over 500 excited electronic states in helium have been identified – their excitation by the energetic electrons in the discharge, followed by their spontaneous radiative decays, the emissions of photons, accounts for the high-resolution spectra of the discharge grayish-white with a tint of blue in color. Of these 500, all of them, high lying in energy, are short-lived radiatively, with the exception, however, of two amongst them. The two have the lowest excitation energy. Their radiative decays to the ground electronic state are deeply forbidden; they cannot decay radiatively. The two form the well-known helium metastables, identified by their spectroscopic designations: $^3S_{1/2}$, the triplet S one half, and $^1S_0$, the singlet S zero – generally referred to in the literature as, the triplet S and the singlet S metastables. Of the two, the triplet S metastable has the lowest excitation energy. It lies at 19.8 electron volts (eV), above the helium ground state. The singlet S metastable lies higher, at 20.2 eV.

Helium atoms in their ground electronic state are chemically inert. A helium atom's two electrons form a closed shell. It cannot enter in a chemical reaction, neither with its own species, nor with any other, as we all know. The situation is, however, far different with every one of the 500 excited electronic states in a helium gas discharge. They are energetically high-reactive, except, and with the exception of the two metastables, they are all *short-lived*, and cannot play an important role.

The effect manifests itself differently in the long-lived metastables, and accounts for their *special dynamic features,* special only to the helium metastables. What follows outlines the effect.

Dynamic Features: Why so Special

By far the majority of the atoms in the helium gas discharge are in their inert, ground electronic states. Once in its energetic metastable state, a helium metastable in the gas discharge encounters in an impact – in a collision – with a helium atom in its ground electronic state. The encounter in the impact is of a short duration in our scale of time, but long in the atomic time-scale, of about 2×10^{-13} second, a fifth of a picosecond. What occurs is strictly wave-mechanical, dictated by the wave nature of the electrons in the atoms. During the encounter, the electron wave functions in the encountering atoms overlap momentarily. A momentary binding occurs. In no ways can one tell during the encounter which electron is which: Electrons are the properties of their wave functions – once overlapped, individual electrons lose their identity, in no way can one tell which is which. As the atoms fly apart, caused by the kinematics of the impact, an *electron exchange* occurs, *wave-mechanically*. The helium atom initially in its ground electronic state, will fly away from the encounter with one of its two electrons now in the *highly excited* energetic *metastable* state. The other, the one initially in the excited metastable state, emerges from the encounter in the *unexcited* ground electronic state.

At a gas pressure in the discharge of about one torr, a millimeter, the mean free-time between two impacts is about one microsecond, a very long time in the scale of the atoms. The helium atom that flew away from the encounter in the metastable state remains in its now metastable state, during the entire mean-free collision time. Once it encounters the next helium atom in its ground electronic state, the act repeats again, a momentary binding occurs, an electron exchange takes place, and a new metastable flying away. The effect repeats over and over again, at about every microsecond. A *diffusion* of the metastability through the helium in the discharge sets in. Depending on the diameter of the discharge tubing, it takes about a millisecond until the helium that emerges from the encounter in the metastable state reaches the walls of the discharge tubing. The act will then *terminate*, in a *most violent* collision effect with the wall. The energetic metastable helium *knocks out* an electron off the wall, as itself emerges from the collision in its ground electronic state – all intact.

With one exception, the encounter between a helium metastable with any species other than of its own kind, a helium, is energetically *highly violent*. The exception is the neon atoms. In encounters with all atomic species other than neon, the metastable helium *knocks out* an electron off the species, ionizes the species, and itself emerges from the encounter in its ground electronic state, intact. The ionizing impacts had attracted so much attentions in the early fifties, the effect in the helium gas discharge in mixtures specially with every other inert gases, had been exhaustively investigated, except with neon. Neon has its ionization potential higher than the two metastable excitation energies. It can not undergo an ionizing impact with either of the two metastables. The mixture with neon had thus been considered uninteresting, and was discarded.

What emerged by the end of the summer of 1958 was the entire theory for the helium neon laser – and the recognition of a deeply wave-mechanical effect, the resonant energy exchange taking place between the energetic helium metastable and an inert neon atom in the discharge gas mixture. In the mixture, a momentary binding occurs between the helium metastable encountering an inert neon atom in the gas discharge. Wave-function overlaps occur for the electrons in the encountering atoms. A *resonant* energy exchange takes place during the encounter. Helium metastable will fly away from the impact in its now ground electronic state, while neon emerges in one of its high-lying excited energy states, at the near-resonant with the helium metastable.

A special effect sets in in the energy exchange, as well. The kinetics of the impact in the encounter enters in satisfying the exact resonance in the energy exchange. The singlet S metastable flying away from the encounter after the energy exchange, will be slightly 'cooler' kinetically, and the triplet S flying away from the encounter after the energy-exchange, will be slightly 'hotter'. The kinetic energy of the impact enters in the energy exchange.

Optical Gain and Amplification Effect

Within weeks, early in the summer of 1958, investigating the energy transfer effect led to the

prediction that there can be inversion and optical gain in two sets of transitions in neon, one as a result of the excitation transfer from the triplet S metastables, and the other a result of the transfer from the singlet S. By far the more challenging task that summer, however, was to estimate theoretically the *values* for the *gain and amplification factors* obtainable for the predicted inverted transitions, and more specifically, for the inverted transitions that will have the highest gain and amplification factors. There followed the theoretical estimates on which relied the entire experimental phase of the work, the planning of it commenced within weeks after my joining the Bell Telephone Laboratory on September of that year.

The set of transitions originating from the triplet S energy transfer to neon, occur in the near-red region of the spectrum, the 1 μm wavelength region. The strongest inverted transition at the highest predicted gain value, lies at 1.15 μm transition wavelength, the spectral laser line that first broke into self-oscillation (see the opening page in this article). The set of transitions originating from the singlet S energy transfer to neon occur in the red-yellow region of the spectrum. The strongest, although at less gain-value than 1.15 μm, occurs at the 0.633 μm in the red.

In the early phase of the investigation, it came to light also that the achievement of the inverted transitions with optical gains, was, interestingly, a *commune occurrence* in gaseous discharges in a variety of the atomic species, including in pure neon. However, the complexities in the excitations by the hot electrons of the high-lying energy levels, and in particular in the presence of the secondary excitation mechanism, and a list of other similar effects, in no way would allow a quantitative estimate of the gain and amplification factors in the inverted transitions obtainable in the gas discharge.

The reliance on the excitations of the high-lying energy levels in neon via the resonant energy transfer from the helium metastables, as per the physics effect I have outlined above, placed at my disposal the one gas discharge system that lent itself to the theoretical estimates of the predicted optical gains and the amplification factor for the inverted transitions.

Without a knowledge of the predicted values for the optical gain and the amplification factor, it would have been in no way possible to perform the experiment.

Experimental Phase

The Bell Telephone Laboratory, considered as a foremost research institution in the country at the time, operated at a $250 million yearly budget – in 1960s' dollars. Transistors had been invented at Bell in the forties. With the awareness at the time at Bell, that a light beam at the degree of frequency-purity and the coherence expected of the laser, will have far-reaching consequences on the telecommunication technology, without hesitation I received from Bell an open ticket to do what it takes – one key person in the administration understood in-depth my approach to the laser – via the gas discharge and the physics effects I had invoked. Within weeks following joining Bell in September, I had my planning underway for what came to be known in a short while later, as a most aggressive research in gas discharges – and at a time when Bell had already, in the summer of 1958, dismantled the entire research activities in gas discharges at Bell. That speaks a great deal for Bell at the time … at the time before the AT&T break up.

In lasers, the knowledge of the full length of the amplifying medium across which the optical gain obtainable at the laser transition will suffice to drive the laser into its self-oscillation, will dictate the full length of the laser interferometer resonator. The spacing between the two high-reflectance interferometer end-mirrors will have to accommodate the full length of the amplifying medium, thus dictating the interferometer full length. With respect to the mirror reflectivity obtainable at the time, one had to be content with the values at the highest close to 98%. The highest gain transition from my theoretical estimates, that of the neon transition at the 1.15 μm wavelength in the near-red, indicated an interferometer length of no less than 50 centimeters, or possibly as long as one meter – and there lay the challenge, achieving the required degree of parallelism needed for the interferometer end-mirrors at such spacing. One could show, from simple inspection, that the parallelism needed for the mirrors had to be at values better than one part in several-hundredths of a wavelength. This value applied to the use of the flat interferometer mirrors known to me at that time.

An alignment to such a degree of accuracy could well be obtainable at the time for Perot–Fabry-type interferometer mirrors at the mirror-spacing not exceeding about eight or ten centimeters at the most – where one would rely on the observation of the interference fringes using the available spectroscopic light sources to observe the fringes, a principle well known in physical optics. At longer mirror spacing, the spectroscopic light sources lacked the degree of coherence, the color purity, needed to observe fringes for the mirror alignment. The fringes will get wiped out.

These days, using a helium–neon laser light source available at every laboratory in optics, one can align a two-mirror interferometer at tens of meters mirror-spacing, or hundreds, or even as far apart as

several miles in some experiments. Ideas are floating around now of the possibility, using gas lasers, to align mirrors placed on satellites in orbit, with the mirror on two different satellites at controlled spacing as far apart as thousands of miles – the experiment thought of is that of the detection of the gravity waves. Without a laser operating and available at the time, in no ways would it have been possible to align an interferometer at a *daring* mirror-spacing as far apart as one meter, or even half as long. One had to rely on an auto-collimator, an optical instrument that at the best would provide an alignment to within one or two wavelengths, nowhere sufficient to drive the laser into its self oscillation.

The challenge mapped the entire course for the experimental phase, foremost aimed at showing every feature of the predicted effects experimentally, from the energy transfer effect, to observing and measuring the gain and amplification effect in the predicted inverted transitions in neon. The feat was that of the art in spectroscopy. The observation of gain and amplification effect was a highlight in the course of the experiment. Up to that point, in optical spectroscopy, one always measured the spectral lines in either emission or in absorption. The feat was the first in spectroscopy, observing the spectral line of an atomic species not in absorption, but in amplification – the amplification of an external light source transmitted through the gas discharge in the experiment. The feat, yet, lay in the art in spectroscopy, throughout the experiments.

The event at 4:20 PM in December two years later, speaks for itself.

> It may seem now, as if one needed an operating helium–neon laser at the time, to align the laser mirrors for the first operating helium–neon laser. It seemed evident from the beginning, that the presence in the very first helium–neon laser, of the optical-gain at the predicted value in the predicted inverted transition, will guide achieving the alignment of its own mirrors, to the exact optical degree of the alignment accuracy needed for the self-oscillation. Driving the laser into its self-oscillation signaled the feat. The feat, however, was that of the power in spectroscopy, making it possible to predetermine the presence in the first helium–neon laser, of the optical gain, at the predicted optimum value needed for self oscillation.
>
> There were doubters and doubters, in the technical staff and the administration at Bell. Donald Herriott, William Bennett and Edward Ballick collaborated with me in the experiment.

The Impact

Within months of the publication of the work in January 1961 in the *Physical Review Letters*, walking through the long hallways at BTL where the laboratories were situated, one could see through the open doors in many laboratories down the long halways, the pink colors of long helium–neon gas discharges plasma tubing, with people in the labs searching for new laser transitions. BTL had revived the gas discharge research activities they had dismantled in the summer of 1958. Not surprisingly, the second set of new laser transitions driven into self-oscillation took place at Bell in 1962, that of the set of transitions in neon originating from the energy transfer from the helium singlet S metastable – with the most intense in the series, that of the by now well-known 0.6328 μm neon transition in the red. There followed the discoveries of the argon–ion gas laser and shortly thereafter the CO_2 gas laser, the two amongst the foremost in the many new gas lasers driven to self-oscillation at Bell.

Every gas laser discovered since the December 12 event, has enjoyed the use of a '*no-longer*' a '*daring*' '*long*' interferometer resonator, merely because one would use a He–Ne laser to *pre-align* the laser mirrors to within a small fraction of the wavelength needed, prior to searching for a new laser line in the gas discharge chosen for the search. The already aligned resonator removed the need to *predetermine* the presence of the gain and the amplification effect at the values needed for self-oscillation. Within a span of about a decade, virtually hundreds of different gases were driven to self-oscillation with this method, operating literally at thousands of different wavelengths, ranging from the far infrared, the 100 100 ηn region, to the near-UV.

The helium–neon laser triggered so many of the key discoveries that followed. Within months, in the spring of 1961, one of the distinguished engineers at BTL, Rudolf Komphner, the discoverer of the backward tube oscillators at the microwave frequencies, began experimenting with the transmission through the improvised thin fiberoptic, of the output beam of a helium–neon laser at the 1.15 μm transition in the near-red, the near-IR, having his eyes on the potential someday in communication on the use of a continuously operating laser light beam at the near-IR frequencies. I recollect the very first ad that appeared on lasers nationally was a BTL ad in the spring of 1961, showing a cross-section of a beam of light, underneath it saying: '*Someday a Beam of Light This Size Will Carry Millions of Telephone Conversations Simultaneously*'. The ad speaks for itself.

In every gas laser, the active laser medium – being a gas – is highly homogeneous. As a result, with a reasonably good optics, one can obtain a nearly perfect Gaussian output beam. For this reason, the helium–neon lasers available commercially since the

mid-sixties, have served as the indispensable tools for the alignment of the complex optics in every research laboratory in lasers, or in every manufacturer of the lasers in the country, or the manufacturers of the precise optical components, or the medical uses and so on.

In the applied areas, the helium–neon laser triggered so many of the key experiments in the early days. Philips at Eindhoven can be considered as the first discoverer of a video disc recorder. The model used a helium–neon red laser, at a most impressive fidelity and color resolution, in recording and in reading for the display. I recollect, in an exhibit shown to me at a Philips Lab, one groove on the recorder was that of a horse in a prairie, and the next groove, one '*micrometer away*' on the recorder, was that of a crowd in a park – so impressive at the time, with no cross talks. They had it packaged in a compact unit already. In other areas, all bar-code readings were done using a helium–neon laser, and some still do.

In the scientific area, from high-resolution spectroscopy at unprecedented accuracy, to the accurate clocks operating at optical frequencies, or in the measurements of the absolute frequencies of the accurate laser clocks, or the early experiments in relativity and so on, all are owed to the precision gas lasers. Helium–neon laser has played the key role, in the early days throughout, and continues today.

A note to the reader

In the early publications on laser, the device was generally known and referred to at the time as the 'Optical Maser'. The word laser became an accepted designation for the device in the late 1960s and the early 1970s.
